COLORADO RIVER SIPHON.*

By George Schobinger, Jun. Am. Soc. C. E.†

With Discussion by Messrs. H. T. Cory and George Schobinger.

Yuma is on the Arizona side of the Colorado River, a short distance below the mouth of the Gila River and about 25 miles north of the Mexican boundary. The bottom lands on both sides of these two rivers, leveed for protection against overflow, together with some mesa land, form the irrigable land of the Yuma Project of the United States Reclamation Service. The water for irrigation is taken from the Colorado at Laguna Dam, a diversion weir 14 miles above Yuma. To conduct the water to the Yuma Valley and Mesa, which is that portion of the Project on the Arizona side below Yuma, it was necessary to construct main canals to, and provide means of crossing, either the Colorado or the Gila. Both rivers have unstable beds, and are subject to sudden floods, which scour out deep channels. Owing to the relative elevations of the water in the canals and rivers, and the great variation between flood stage and low-water stage, a crossing by an aqueduct over either river would have been impossible, and an inverted siphon crossing was the only practicable one. For reasons of economy in the construction of both canal and crossing, the Colorado River siphon was selected. As may be seen on the general map, Fig. 1, the siphon is near Yuma, and a short distance below the Southern Pacific Railroad Bridge. The river at this point flows be-

tween high banks which restrict its meandering tendencies and permit a shorter tunnel than would be possible at other points.

The variation between extreme flood and low-water surface elevations has been as great as 18 ft. This, however, does not represent the variation in cross-section; it has been said that for every foot the river rises it scours out its bed 2 ft., and the cross-sections on Fig. 9 illustrate the approximate truth of the statement. The deepest scour within recent years is shown; this section was taken at the river gauging station 600 ft. below the line of the tunnel, the width of the river being the same at both points. At the periodic high-flood years the scour is always approximately the same. In the intermediate low-flood years the 30-ft. silt blanket dropped by the falling river of the preceding years is only partly removed.

Borings taken on the line of the tunnel indicated a bed of soft sandstone underlying the silt. It was thought that, by working at a sufficient depth, open tunneling could be carried on without great interference from seepage water. Therefore, preparations were made for sinking shafts on each side of the river, with the intention of following this method of construction.

Before describing the construction in detail, a few words may be said of the general dimensions of the work. The California shaft is 130 ft. from the center of the levee, and 250 ft. from the Southern Pacific Railroad. The Arizona shaft is in high ground, 200 ft. from the river, and 955 ft. from the California shaft. The canals conducting the water to and from the shafts have a bottom width of 80 ft., a water depth of 7 ft., and carry 1 400 sec-ft., at full capacity, which is sufficient for the irrigation of about 100 000 acres. The siphon was designed to operate at full capacity with a loss of head of 2 ft. When operating at less than full capacity the same loss of head is obtained by throttling the flow at the intake; thus the water surface at the intake and outlet are maintained uniformly at Elevations 132 and 130, respectively. The inside diameter of the California shaft is 17 ft., and that of the Arizona shaft is 23 ft. The elevation of the tunnel flow line is + 49 at the shafts and + 47 in the middle of the river.

The assumed maximum conditions of loading to which the tunnel is subjected are, (*a*) tunnel empty, with pressure on the outside only, due to a hydrostatic head of 74 ft., at high stage of the river, and (*b*)

FIG. 1

system in operation, at low stage of the river, with pressure on the inside due to a hydrostatic head of 76 ft., partly balanced by a head on the outside of 59 ft. Under these conditions, both the tensile and compressive stresses in the 2-ft. thick tunnel lining are very low. The many uncertainties as to the actual loading from the material through which the tunnel passes, and the desirability of a fairly water-tight job, fully justify the thickness of the tunnel walls as constructed.

The stresses in the completed shafts due to the static loads would be considerably less than those in the tunnel, as the lining of both shafts is 3½ ft. thick and is further reinforced at the bottom by the quarter-turn lining. The most severe conditions to which the shafts were subjected were those due to the method of construction, which was to sink them as open caissons. As these would be largely a matter of conjecture, there would be small profit in attempting to compute the stresses. Important determining factors in fixing the thickness of the lining were the probable skin friction and the weight required to sink the caisson. As a guide in determining the thickness necessary to resist the stresses during the sinking and to furnish weight to overcome the skin friction and give a water-tight shaft, comparison was made with a number of like structures built under similar conditions. These showed a variation in thickness of walls of from 2½ to 6 ft., and, in the skin friction overcome in sinking them, of from 300 to 700 lb. per sq. ft. The thickness was fixed at 3½ ft., with no reinforcement, except a small number of short rods used to bond adjoining sections.

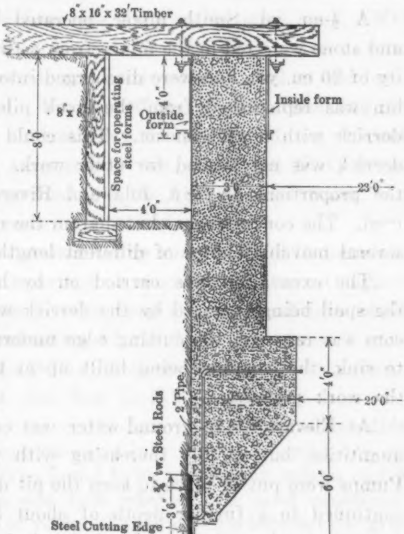
Arizona Shaft.

The cutting edge consisted of a cylindrical skin plate, ½ in. thick and 3½ ft. wide, bent on a circumference of 30 ft. diameter. It is reinforced near the bottom edge by a 10-in., 25-lb. channel with its web riveted to the inside of the plate. To the top flange of the channel is riveted a horizontal 14½ by ½-in. shoe plate, stiffened at its inner edge by a 3 by 3 by $\frac{7}{16}$-in. angle, and connected to the channel at sixteen points on the circumference by vertical plate and angle brackets. The outside of the shaft concrete is flush with the outside of the circumferential plate. On the inside, the concrete batters in from the shoe plate to a diameter of 20 ft. at a point 6 ft. above the cutting edge, giving a thickness of concrete of 5 ft. at this point. The inside face is vertical for 4 ft. above this, and then steps out to the normal

inside diameter of the shaft, which is 23 ft. The rivet heads on the outside of the cutting edge skin plate were countersunk, in order to reduce the friction.

In preparing to sink the shaft, a pit, some 40 ft. in diameter and 12 ft. deep, was excavated, using teams and scrapers. The bottom was leveled and the cutting edge assembled and placed. Wooden forms were constructed for the lower 10 ft. of the shaft, and the concrete was placed. The steel forms, which were used throughout the shaft construction, were then set in place.

To support the forms, twelve 8 by 16-in. timbers, 32 ft. long, were set on radial lines projecting as cantilevers over the shaft walls, the outer ends being firmly anchored in the ground. Bolts passing through these timbers carried the forms. As may be seen on the section, Fig. 2, the inside of the shaft was thus left open, so that excavation could be carried on without interference by other work. A passage was also left on the outside of the shaft to give access to the outside form.



HALF SECTIONAL ELEVATION

FIG. 2.

The forms were built in segments of a cylindrical surface, with $\frac{3}{16}$-in. plate, 4 ft. high, stiffened at top and bottom by circular ribs of built-up channels with horizontal web. The segments were connected so that, when they were assembled and in place, the circumference of the whole could be increased or decreased by turnbuckles. Thus, when the concrete had been built up, as previously described, the inside and outside forms were fitted to the completed concrete, with a vertical lap of about 2 in., and were plumbed, and clamped in place

by tightening the turnbuckles. No braces, ties, spreaders, or other means of support were required. When the forms had been filled with concrete, the hanger-bolts were released; excavation proceeded through the open space in the center of the shaft, and, as the caisson sank, the forms traveled with it. In preparing for a new lift of concrete, the turnbuckles were released, the forms were pried from the face of the concrete, raised to their original level with the derrick or tackles supported from the cantilever timbers, and reset as before. In this way a shaft wall of uniform thickness and very smooth surface was obtained.

A ½-cu. yd. Smith mixer, operated by steam, was used. Sand and stone were fed to the mixer from a two-pocket bin, having a capacity of 20 cu. yd., and were discharged into the measuring hopper. The bin was replenished from the stock piles directly back of it, by a derrick with a grab-bucket. This could be done at times when the derrick was not needed for other work. The concrete was mixed in the proportions 1 : 2½ : 5, Iola and Riverside Portland cement being used. The concrete was chuted from the mixer directly into the forms, several movable chutes of different lengths being used.

The excavation was carried on by hand, with pick and shovel, the spoil being removed by the derrick with a 1-cu. yd. bucket. The core was removed, the cutting edge undermined, and the shaft allowed to sink, the concrete being built up at the surface in 3½-ft. lifts as the work progressed.

At Elevation 120 ground-water was encountered, at first in small quantities, but rapidly increasing with the depth below this plane. Pumps were put in place to keep the pit dry, and hand excavation was continued to a further depth of about 50 ft. Here the excess hydrostatic head on the outside of the shaft was sufficient to cause sudden inrushes of water and sand under the cutting edge, and it was found necessary to change the method of excavation. The core was now removed by clam-shells to a depth of from 5 to 10 ft. below the cutting edge. Divers then drilled holes in the supporting ring under the cutting edge and placed small charges of dynamite. These, when fired, caused the shaft to sink varying distances.

When the cutting edge had penetrated some distance into the bed of soft sandstone indicated by the borings, attempts were made to seal the shaft to the undisturbed hard material by sinking pipes from

the surface outside of the caisson walls and forcing grout through them into the running sand. It was thought that by impregnating with grout the soft ground surrounding and for some distance above the tunnel opening, the flow of water might be sufficiently cut off to permit of open tunneling into unfissured, less pervious ground. After the grouting was complete a concrete plug was placed in the bottom of the shaft under water, and the water was pumped out. Preparations were made for tunneling operations. Cage guides and a gallows frame were constructed and hoisting machinery was erected. An open crib was built on top of the shaft, and a working floor laid. Tracks were laid from the mixer to the shaft and from the shaft to the spoil bank. While work was under way cutting through the shaft walls for a tunnel opening, other "blows" of water and sand occurred, and at the last of these the work was flooded. Further efforts at open tunneling were then abandoned, it being evident that the grout had not efficiently consolidated the material surrounding the shaft, and that the soft and porous nature of the ground and the high head of water would make it necessary to work under compressed air.

The foregoing method of consolidating running sand in foundation and similar work has been described as successful in several engineering writings. The outcome in this case showed conditions similar to those found in the construction of the New York tunnels of the Pennsylvania Railroad. The following is quoted from a discussion by the late C. L. Harrison, M. Am. Soc. C. E.*

"Grout was used extensively in the face in an effort to consolidate the material. In digging out the sand into which the grout had been injected under pressure, it was found to be collected in masses and not generally distributed; this was true whether the sand contained a large or a small percentage of voids. The interstices between the grains of sand were too small to permit the free flow of grout into them; however, grouting in the face did compact the material to some extent and reduce the flow of air through it."

Francis L. Sellew, M. Am. Soc. C. E., says:†

"In the writer's judgment, it is impracticable to so consolidate fine sand by the injection of grout that the resulting material will serve any useful purpose. While sufficient pressure may be used to cause penetration, the fluid will move at such low velocities that the grout will set up before any appreciable distance has been traveled.

* *Transactions*, Am. Soc. C. E., Vol. LXIX, p. 400.

† "The Colorado River Siphon," *Engineering News*, August 29th, 1912.

It is believed that success attained by this method will be confined to coarse materials."

CALIFORNIA SHAFT.

The work at the California shaft will not be described in detail, as the methods and results were similar to those at the Arizona shaft, except as to the dimensions of the shaft, which have been mentioned elsewhere. The ground through which the shaft passes is somewhat more varied in character, as may be seen by reference to Fig. 14. The final grade, as originally contemplated, was somewhat lower than on the Arizona side, but the difficulties of construction were such that the final elevation of the cutting edge was fixed at 28 ±; and the bottom of the shaft was sealed at that elevation.

WORK UNDER COMPRESSED AIR.

When it became evident that, owing to the shattered and porous condition of the material surrounding the shaft, open tunnel methods were out of the question, a Consulting Board, consisting of Louis C. Hill, M. Am. Soc. C. E., Supervising Engineer; Francis L. Sellew, M. Am. Soc. C. E., Project Engineer, of the United States Reclamation Service; and Silas H. Woodard, M. Am. Soc. C. E., formerly Division Engineer on the East River Tunnels of the Pennsylvania Railroad, made an investigation of the existing conditions, and advised a change in method to tunneling by the pneumatic process, the work to be carried on from the Arizona shaft only.

A compressor plant was rented from Charles A. Haskin and Company, Tunnel Contractors. Owing to the impossibility of securing suitable labor, skilled in such work, in that part of the country, experienced "sand-hogs" were brought from the East, to form a nucleus of trained compressed-air tunnel men. E. C. Hayden, Assoc. M. Am. Soc. C. E., was Superintendent of Construction on the work from this time until the successful completion of the tunnel. The rented equipment was as follows: Three Ingersoll compressors: 20 by 30-in., 24½ by 24-in., and 17 by 24-in; vertical and horizontal air locks and equipment, medical lock, air receivers and coolers, and the 4-ft. steel shafting used above the air deck.

The rated capacity of the compressor plant was 4 000 cu. ft. of free air per minute compressed to 40 lb. The maximum consumption for 24 hours averaged 2 000 cu. ft. per min., or about 55% of the rated capacity. The maximum recorded consumption for a short time

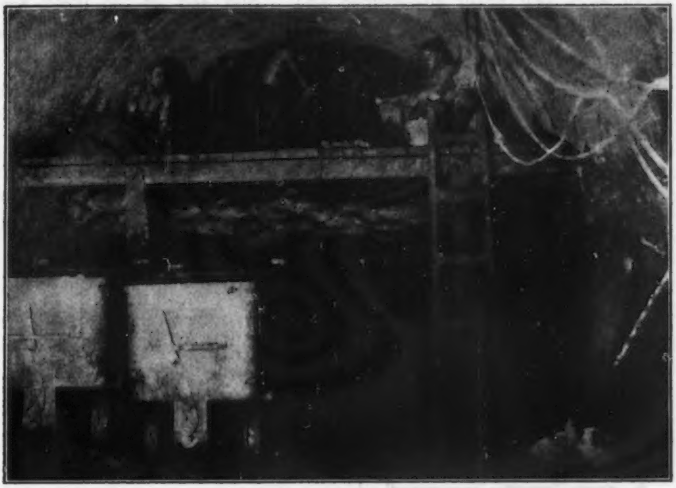


FIG. 3.—SAND-BAG BULKHEAD. EXCAVATING IN HEADING.

FIG. 4.—VIEW OF TUNNEL.

was 2 200 cu. ft. per min. The compressor plant was thus never seriously taxed for a long period. The average consumption during the tunneling operations was 1 450 cu. ft. of free air per minute, to a pressure of 28 lb. per sq. in.

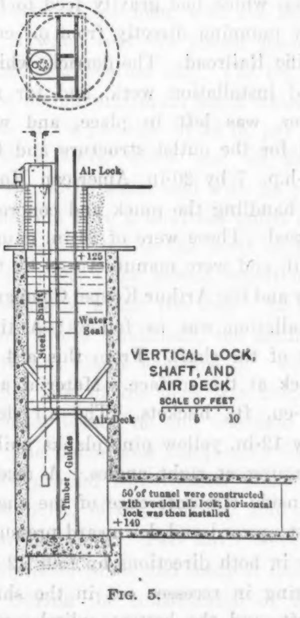

FIG. 5.

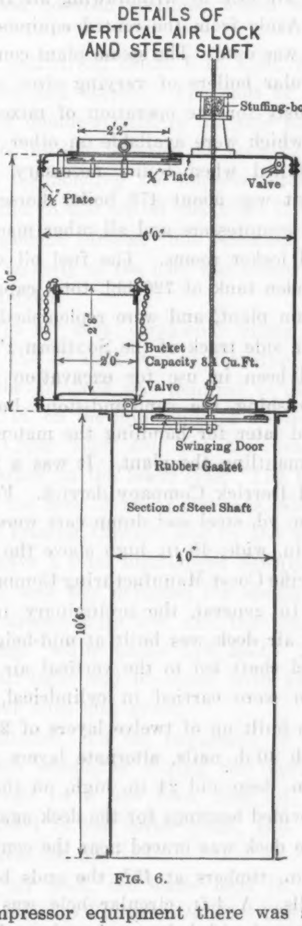

FIG. 6.

In addition to the foregoing compressor equipment there was already installed a 12½ by 14-in. Ingersoll-Rand high-pressure machine, with a capacity of 200 cu. ft. per min. at 100 lb. This had been used during grouting operations at the Arizona shaft, and, during the

further prosecution of the work, was used for operating drills and the concrete lock, and also as emergency equipment at times when the consumption of air was great, or when it was not advisable to fill the air lock by withdrawing air from the heading.

Aside from the rented equipment, that which was already on the job was used. The steam plant consisted of five oil-burning, horizontal, tubular boilers of varying sizes, some of which had been used previously for the operation of mixers, hoists, derricks, etc., and others of which were available on other parts of the Project and were later installed when found necessary. The total rated capacity of the plant was about 475 boiler horse-power. This served for operating the compressors and all other machinery, and for heating the change and locker rooms. The fuel oil was stored in one concrete and one wooden tank of 720 bbl. total capacity, which had gravity feed to the steam plant, and were replenished by pumping directly from oil cars on a side track of the Southern Pacific Railroad. The derrick, which had been in use for excavation and installation work, and for replenishing the sand-and-stone hopper, was left in place, and was used later for handling the material for the outlet structure and for dismantling the plant. It was a 20-h.p., 7 by 20-in. American Hoist and Derrick Company derrick. For handling the muck and concrete, ½-cu. yd. steel end dump cars were used. These were of 24-in. gauge, 24 in. wide, 40 in. high above the rail, and were manufactured by the Pacific Coast Manufacturing Company and the Arthur Koppel Company.

In general, the preliminary installation was as follows: A timber air deck was built at mid-height of the shaft. From this a 4-ft. steel shaft led to the vertical air lock at the surface. Material and men were carried in cylindrical, 8-cu. ft., buckets. The air deck was built up of twelve layers of 2 by 12-in. yellow pine planks nailed with 40-d. nails, alternate layers running at right angles. A recess, 4 in. deep and 24 in. high, on the inside circumference of the shaft, provided bearings for the deck against upward and downward pressure. The deck was braced near the center in both directions by four 12 by 12-in. timbers at 45°, the ends bearing in recesses cut in the shaft walls. A 4-ft. circular hole was left, and the bottom cylinder was fastened with bolts passing through its flanges and the air deck. Other holes were left for pipes for air supply, electric light, and telephone wires.

From the deck to the surface was 72 ft. Six sections of 4-ft. cylindrical steel shaft were used. These were made up of ¼-in. steel plate with lap-riveted joints and 4 by 4 by ½-in. angle flanges at the top and bottom. Gaskets were used between sections, which were bolted together through the flanges.

The vertical air lock was a 6-ft. cylindrical drum, 6 ft. high, with 2½-ft. circular plate doors in the top and bottom. The ends of the drum were of ⅝-in. plate, dished and double-riveted to the side plate, which was ⅜ in. thick. The 8-cu. ft. buckets cleared the opening by about 1 in. all around. The cable for hoisting the buckets through the steel shaft passed through a gland in the top of the lock; it was of especially compact texture and smooth surface, thus reducing the leakage of air to a minimum. The capacity of the lock was about five buckets, or ten men, with the lock-tender.

A water seal was placed above the air deck, completely filling the shaft to Elevation 129. The top of the air deck was at Elevation 85. The actual maximum loads which the air deck was required to carry were (*a*) a pressure of 36 lb. per sq. in. on the lower side of the deck, with a 43-ft. water seal on the upper side, and (*b*) the weight of the 43-ft. water seal with no pressure on the lower side. The first condition gave a total net uplift on the deck of about 500 tons, which was transmitted to the shaft by the bracing timbers, and by the deck at its edge. The second condition gave a total unbalanced downward pressure of about 700 tons. As the deck was designed for somewhat more severe conditions, the actual stresses were low, and the timber gave but slight evidence of "working" while under full load. The under side of the deck was made air-tight and fire-proof with sheet asbestos tacked on and plastered over with clay-grout.

The boiler and compressor installation and the remainder of the above-ground construction plant were completed during this period. The hoist, mixer, derrick, and change room had been used on the previous work. Two units were added to the boiler plant, and the compressor plant and medical lock were set up.

During the construction of the air deck, the water level in the shaft had been kept down by pumps about to Elevation + 80. The air pressure was now raised and the water blown and pumped out. The relation between the river water surface and that in the shaft, with the air pressure, showed that the soft and porous material surrounding

and underlying the shaft offered small resistance to the transmission of hydrostatic pressure. When the water level had been lowered to + 42, the pressure was 36 lb. per sq. in. At that time the river water surface was at about 122. Elevation 42 was set as the bottom elevation of the concrete plug. Allowing for the thickness of the plug, and the sump, this brought the elevation of the flow line of the tunnel at + 49. The following considerations influenced the fixing of this grade:

First, the tunnel constructed from this elevation would have a minimum cover at high stage of the river of about 15 ft., which was considered sufficient for safety of construction in this material. As a matter of history, the tunnel did not reach the deepest point of the river until after the flood period, and the cover at that time was more than 30 ft.

Second, there was no assurance that the ground would be more favorable lower down.

Third, the difficulties, slowness, and expense of construction increase greatly with higher pressures.

The plug in the bottom of the shaft was designed as a circular reinforced concrete diaphragm, supported at the edge, to resist the maximum hydrostatic pressure, which at highest stage of the river would be about 40 lb. per sq. in. It seemed probable that the diaphragm would receive its full load while the concrete was still comparatively new. In order to make it possible to relieve the pressure somewhat, ten 2-in. pipes were set, to pass through the plug; the lower ends were nested in crushed rock to insure a free opening, and the upper ends were furnished with globe valves.

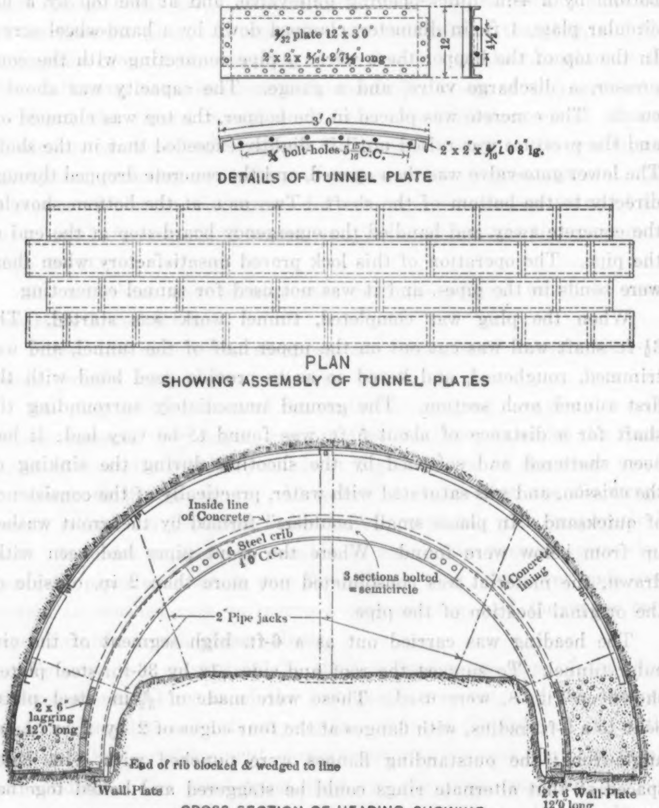
To provide a support in the shaft walls for the edge of the plug, a circumferential recess of the full height was cut, and the concrete was roughened to a depth varying from 3 in. at the top to 7 in. at the bottom. Any reinforcement encountered was cut and bent out to aid in bonding. The reinforcing steel for the plug consisted of $\frac{3}{4}$-in. and 1-in. square twisted rods, and old 15-lb. industrial rail. It was lowered into the shaft through an improvised pipe-lock. A 4-in. pipe was used, with a gate-valve at the top and a board flap-valve at the bottom. The bottom being capped, the steel was lowered from the top until its end rested on the board-valve. The top was then closed and the pressure equalized; the rods were dropped through and on a platform, and were then set in place. In this way steel was lowered as

fast as it could be set. Concrete was lowered in buckets through the 4-ft. steel shaft from the vertical air lock at the surface, and also through a small material lock. This consisted of a hopper closed at the bottom by a 4-in. quick-opening gate-valve, and at the top by a flat circular plate, 1 ft. in diameter, clamped down by a hand-wheel screw. In the top of the hopper there were: a pipe connecting with the compressor, a discharge valve, and a gauge. The capacity was about 3 cu. ft. The concrete was placed in the hopper the top was clamped on, and the pressure was raised until it slightly exceeded that in the shaft. The lower gate-valve was then opened, and the concrete dropped through directly to the bottom of the shaft. Two men at the bottom shoveled the concrete away and handled the emergency board-stop at the end of the pipe. The operation of this lock proved unsatisfactory when there were bends in the pipes, and it was not used for tunnel concreting.

When the plug was completed, tunnel work was started. The $3\frac{1}{2}$-ft. shaft wall was cut out on the upper half of the tunnel, and was trimmed, roughened, and keyed so as to provide good bond with the first tunnel arch section. The ground immediately surrounding the shaft for a distance of about 5 ft. was found to be very bad; it had been shattered and softened by the shooting during the sinking of the caisson, and was saturated with water, practically of the consistency of quicksand. In places small "boulders" formed by the grout washed up from below were found. Where the grout pipes had been withdrawn, the material was consolidated not more than 2 in. outside of the original location of the pipe.

The heading was carried out as a 6-ft. high segment of the circular tunnel. To support the roof and sides, 12 by 36-in. steel plates, shown on Fig. 8, were used. These were made of $\frac{3}{32}$-in. steel plate, bent to a 9-ft. radius, with flanges at the four edges of 2 by 2 by $\frac{5}{16}$-in. angle-irons; the outstanding flanges were punched with $\frac{3}{4}$-in. holes spaced so that alternate rings could be staggered and bolted together with $\frac{5}{8}$-in. bolts. The breast was boarded and clayed tight. The ground was cut out on the circumference the size of one plate, and the plate set and bolted. The space between the plate and the roof was filled with clay. In this way a ring was completed from the crown to about 3 ft. above the springing line on each side. Trench braces were set radially on every second or third ring. The breast was then cut down level with the bench breast-boards, reset, and clayed, and the process

repeated. The joints between plates and between rings of plates were clayed over and mud-washed at intervals. Empty sacks and clay sacks were used for " blows."



CROSS-SECTION OF HEADING SHOWING TUNNEL PLATES, BRACING, CONCRETE FORMS, ETC.

FIG. 7.

When an advance of fourteen rings beyond the finished work had been made, the heading, roof, and breast were tightened, the pressure was raised from 2 to 3 lb., and side trenches were cut to the springing line. Wall-plates were set to line and grade, steel forms set, and the 2-ft. concrete lining was placed. The forms were 6-in. channels bent

to a radius of 6 ft. 10 in., the 6-in. dimension being radial; they were in three sections for the semicircle, and fastened with ⅝-in. bolts. The lagging was 2 by 6-in. surfaced lumber, 12 ft. long. The longitudinal joint at the springing line battered from face to back in such a way as to facilitate grouting and caulking the joint on the completion of the invert concrete.

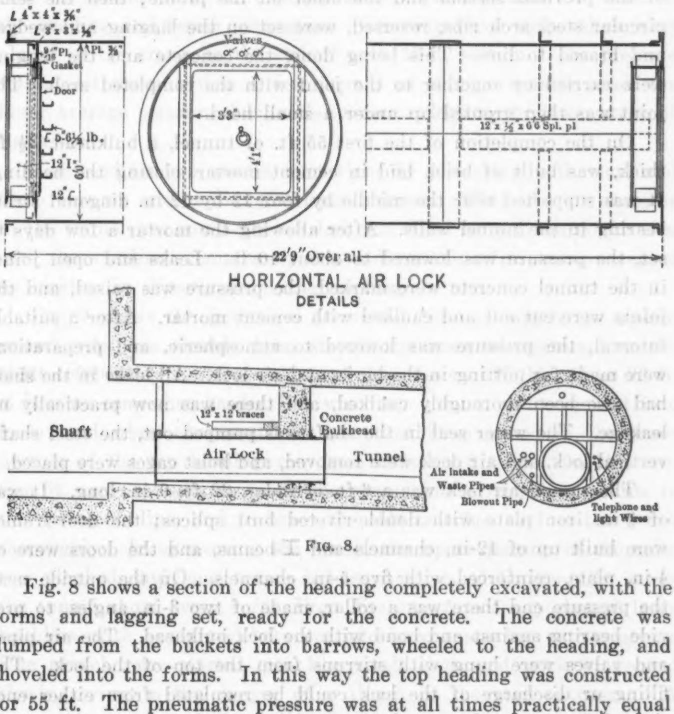


Fig. 8.

Fig. 8 shows a section of the heading completely excavated, with the forms and lagging set, ready for the concrete. The concrete was dumped from the buckets into barrows, wheeled to the heading, and shoveled into the forms. In this way the top heading was constructed for 55 ft. The pneumatic pressure was at all times practically equal to the hydrostatic head. The bench was then excavated in sections of from 10 to 12 ft. For this the pressure required was from 4 to 6 lb. higher than for the heading. Sections of bench lapped with sections of heading, so that there was no joint in the entire tunnel on one plane. The arch concrete carried itself on about a 10-ft. span longitudinally, during the concreting of a section of invert. In excavating the bottom, it was seldom necessary to brace the sides, except immediately

under the arch concrete. Here 16-ft. trench braces were set across the full width. The sand was kept plastered with clay to within a few feet of the bottom. When the excavation was completed, profile bulkheads were set at the end, to line and grade, and the bottom was filled with concrete to a level with the tops of the profiles. On the concrete there was then laid 12-ft. lagging, one end lying on the finished work of the previous section and the other on the profile; then the semicircular steel arch ribs, reversed, were set on the lagging and wedged and braced to line. This being done, the concrete and the lagging were carried up together to the joint with the completed arch. The joint was then grouted up under a small head.

On the completion of the first 55 ft. of tunnel, a bulkhead, 3½ ft. thick, was built of brick laid in cement mortar, closing the heading. It was supported near the middle by four 12 by 12-in. diagonal struts bearing in the tunnel walls. After allowing the mortar a few days to set, the pressure was lowered to about 10 lb. Leaks and open joints in the tunnel concrete were marked, the pressure was raised, and the joints were cut out and caulked with cement mortar. After a suitable interval, the pressure was lowered to atmospheric, and preparations were made for putting in the horizontal air lock. All leaks in the shaft had also been thoroughly caulked, and there was now practically no leakage. The water seal in the shaft was pumped out, the steel shaft, vertical lock, and air deck were removed, and hoist cages were placed.

The tunnel air lock was a 6-ft. cylinder, 22 ft. 9 in. long. It was of ⅜-in. iron plate with double-riveted butt splices; the door-frames were built up of 12-in. channels and I-beams, and the doors were of ½-in. plate, reinforced with five 5-in. channels. On the outside near the pressure end there was a collar, made of two 3-in. angles, to provide bearing against and bond with the lock bulkhead. The air pipes and valves were hung with stirrups from the top of the lock. The filling or discharge of the lock could be regulated from either end, there being a double set of 2-in. supply and discharge valves. The capacity of the lock was five ½-cu. yd. cars.

The bulkhead was of plain 1 : 2½ : 5 concrete, 4 ft. thick, with two sets of diagonal braces against the tunnel walls. Bearing on the circumference was provided by a 3-in. recess which had been left in the concrete lining on this section. Pipes for air supply, telephone and electric light wires, and drainage were concreted in.

When this work had been completed (October 20th, 1911), the pressure was again raised and the temporary brick bulkhead was cut out. The method of advancing the heading has already been outlined, and in general this method was adhered to throughout the construction. Sandbag and clay bulkheads were placed in the lower half of the tunnel at the end of the completed work during the advance of the heading, the pressure usually varying from 3 to 5 lb. on the heading and bench excavation. Grouting pipes with valves were placed in the crown at the end of each 12-ft. section. The pressure was at all times within a few pounds of the hydrostatic head, the lower average pressure during the winter reflecting the lower stage of the river.

The heading was always kept tight by plastering with clay, and there were no serious blows of long duration. While the air chamber in the tunnel was small, the air lock was filled by a direct connection with the auxiliary compressor, to avoid variations in pressure caused by locking in directly from the heading.

Fig. 9 shows the geological formation through which the siphon passed. As has already been stated, the material surrounding the shaft softened during the sinking of the caisson. Within 15 or 20 ft. it became somewhat harder, but was very porous, and crumbled into loose sand when excavated. A pocket of loose gravel in the lower portion of the top heading ran from Stations 3 to 5. On this section it was necessary to carry the tunnel plates or poling boards to the springing line, and to brace the side trenches against the bench thoroughly. In excavating the bench, the upper portion of the sides was planked, and long trench braces were placed horizontally across the tunnel about every 4 ft. From Stations 5 to 7 a pocket of large boulders, with pea gravel between, interfered somewhat with progress. The gravel, once started, ran like small shot, and work progressed slowly, owing to the danger of a slump in the roof or breast. A lense of exceedingly hard and thoroughly cemented gravel, or puddingstone, was encountered between Stations 5 and 6. The last 300 ft. brought to light various pockets, large and small, of boulders, clay, gravel, and quicksand. Both experienced prospectors and amateur miners were disappointed in not finding gold-bearing gravel under the Colorado, although an incipient boom was started by salting a car of muck with brass filings.

From Station 7 to the California shaft the material was somewhat more favorable, and progress was steady. On April 12th a galvanized-iron well casing was encountered. This was one of the original test

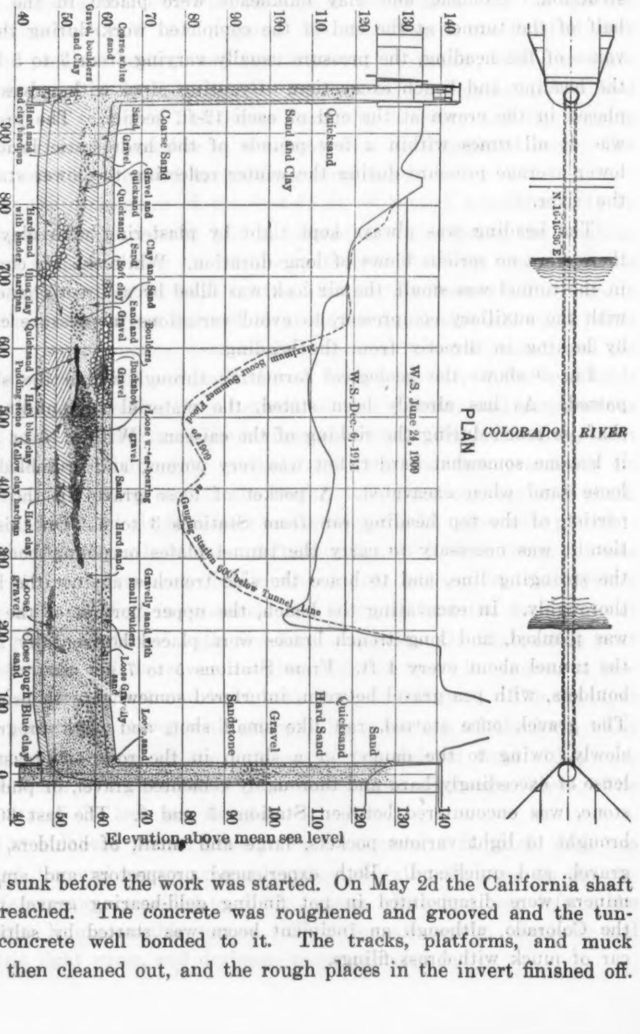

Fig. 9.

wells sunk before the work was started. On May 2d the California shaft was reached. The concrete was roughened and grooved and the tunnel concrete well bonded to it. The tracks, platforms, and muck were then cleaned out, and the rough places in the invert finished off.

The pressure was dropped to 5 lb., and all leaks, cracks, and porous spots were marked; then the pressure was raised to 30 lb., and the leaks were caulked. The tunnel was then opened for inspection. The leaks remaining were insignificant, and the work all appeared to be in good condition. The lock bulkhead, lock, and cage guides were removed, and the quarter turn in the bottom of the Arizona shaft, described elsewhere, was constructed.

From the time of the installation of the horizontal lock to the time of completion of the tunnel, the average progress was 4½ ft. per day. The best monthly progress was 165 ft., in favorable ground, during January, 1912. The slowest progress was during February, in gravel, boulders, and sand; in this month a length of 100 ft. of tunnel was completed.

Alignment.

The elevation of the flow-line at the shafts is + 49. For 100 ft. from each shaft the grade is 2% down, and between these points the bottom is level. The line is straight between shafts.

On the surface a parallel offset line was run, there being obstructions on the direct line. After pumping out the Arizona shaft, and previous to the construction of the air deck, the surface line was plumbed down and plugs were set in the shaft walls. After the installation of the horizontal air lock, the surface line was brought down and carried through the lock four times, to eliminate errors. The detailed operation was as follows:

The transitman, setting up on the surface line, directed the placing of two 2 by 3-in. wrought-iron staples, on each side of the shaft, the line falling within the cross-bar of each staple. These were driven into the solid crib timbers inclined over the shaft, at such an angle that the plumb line, hanging over them, would clear all obstructions below. The line was marked on the bar with a file, and the steel wire plumb lines, carrying 20-lb. plumb-bobs, were placed in the file marks. The transitman, by moving the telescope only slightly, or not at all, in a vertical direction, could then observe both wires directly below the points of support, sighting between the legs and over the top of the nearer staple. The plumb-bobs were hung in pails of water. The length of the base line thus obtained was 10 ft. 6 in.

A 4 by 6-in. timber was placed across the tunnel end of the air lock, and securely wedged and braced. The transit, on a small trivet,

was set on this timber and lined in by sighting on the plumb wires, oiled paper and a candle being used for illumination. A scratch was made on line on the far end of the lock, above the door. A second transitman stayed in the shaft to observe the lock for motion due to jarring or working while the pressure was raised. The first transitman then locked through, checked his setting on the mark over the lock door, plunged his transit and took readings on two scales fixed in the tunnel roof at 30 and 100 ft. from the lock. Without lifting the transit, the operator again locked out and checked on the position of the plumb wires in the shaft. If the check was unsatisfactory, the line was again locked through and back. The transit was once more set up on the surface and the position of the wires was checked back to the original line, thus completing the circuit. While the alignment work was being done, one of the two cages was out of commission, the plumb lines occupying the one cage well. The work was done at a time when all material could easily be handled with one cage.

The level-work differed in no way from surface leveling, a point in the lock being used as a turning point. At each setting of the forms, a grade nail was set in the breast.

In carrying forward the line as the work in the tunnel progressed, two 2-in. wrought-iron staples were driven into the roof at the end of every 60-ft. section, on line and about 15 ft. apart. The exact line was marked with a file on the cross-bar of each staple, and a plumb line was hung in the file mark. The work of setting the forms preceding each run of concrete was done with a rule, a string, a plumb-bob, and a carpenter's level.

The string was stretched to the breast, tangent to plumb-lines hung in the file marks, and nails were set in the breast and at the end of the completed work. Between these was stretched a line, from which the foreman afterward could check the setting. Measuring from this line, the wall-plates were set in the side trenches, exactly to line, and approximately to grade. The first form was brought in, bolted up, and set nearest the breast, the ends, which were on the horizontal diameter, being braced securely to line, as given by the wall-plates on which they rested. The grade was then checked from the nail in the breast, and the rib was shimmed up to the proper level. The intermediate ribs were then set up and quickly aligned between the pilot form and the completed concrete. The cross-section was then measured

up, and what slight trimming and shaping remained was done in a short time. The concrete of the preceding section was cleaned and roughened, and the new run started.

The setting of the forms for the invert was somewhat simpler. A profile-bulkhead was constructed, made up of three thicknesses of 1-in. planks, the radii of the upper and lower edges of the profile corresponding to the inner and outer radii of the concrete lining. It was cut on radial lines into interchangeable sections 3 ft. long, the edges being bound with iron and carefully trued. When the excavation of a 10-ft. length of invert was complete, the profile was set up at the end of the section, the line and grade being measured from the completed concrete of the arch. The bulkhead was secured on the concrete face by iron pins driven into the ground, and was wedged and braced against the bench. As has been previously outlined, the bottom was filled with concrete; 12-ft. lagging was then laid on the concrete, one end resting on the completed work and the other end on the profile. The arch ribs, reversed, were set on the lagging, and secured against uplift by wedges and a cross-brace. The lagging and the concrete were then carried up together. The same set of profiles was used throughout the work. It was impossible to check the line and grade at the California shaft until the tunnel lining was complete and sealed to the shaft. The differences, however, were inappreciable, and the adjustment was made in the 3½-ft. thickness of the shaft lining.

Caisson Disease.

Doctors Henri ApJohn and O. I. Tower were medical examiners for the Reclamation Service. A certificate signed by the examiners was required before a man was employed at tunnel work.

The proportion of green men was necessarily very high, as there has been no compressed air work of any magnitude in the region supplying Yuma with labor. About twenty seasoned men, including the foremen, were brought from the East, and this group remained throughout the work. The remainder of the force shifted constantly; it was composed largely of Mexicans and "floaters" who came to spend the winter in Yuma. The conditions, therefore, were unfavorable, as far as the physical make-up and the seasoning of the laborers were concerned.

At the start, when the pressure rose above 30 lb., it was found

necessary to cut down the time spent under compressed air, so that the gangs worked a total of 4 hours in the heading during an 8-hour shift. The larger number of cases of "bends" at the start, under conditions apparently favorable as to air supply, was undoubtedly due to the fact that the highest pressures, averaging more than 35 lb., came at a time when the majority of the force was composed of green men. However, with the short shifts, there were no fatal cases. Later, although the pressure was at times as low as 27 lb., the same hours were adhered to, it being impracticable to vary the schedules with the varying pressures.

The time of locking out was fixed at from 12 to 15 min., the rate of decompression being made constant. This rule was rarely violated, except by the lock tenders, who were in and out at very short intervals, and whose tissues were never "saturated" by air under pressure. A medical lock, similar to those used on the East River Tunnels, was used for recompression and treatment of cases of "bends."

The total number of different men employed on compressed air work, from start to finish, was about 1 300. All these men had at one time to pass the medical examination. Some who were passed at first, but who were very susceptible, were eliminated later. However, in those cases in which the symptoms were merely pains in the extremities, which were relieved by recompression or local treatment, the men were at liberty to return to work at their pleasure. As the work was done in a small town, and the men lived at the Government bunk-house or at the other rooming houses close at hand, there were probably no serious cases which escaped the notice of the physicians. The records show the following cases treated:

(1) Cases causing disability for a few hours.......	299
(2) Cases causing disability from one to three days.	38
(3) Cases of partial paralysis, including bladder and lower extremities, causing disability for a few weeks	4
(4) Cases of total paralysis, resulting in death in three weeks..................................	1

Those in Groups (1) and (2) were largely cases of pains in the arms or legs, with a few cases of vertigo. These were numerous at the start; the most susceptible men, having suffered once, were usually

willing to leave the work after the experience; these cases, therefore, became of less account as the work progressed. The cases in Group (3) were not traceable to extraordinary conditions on the work at the time of their occurrence. They were scattered, and did not coincide with any noticeable increase in the other cases, and must be laid to unknown factors in the condition of the men at the time. The one death was of a seasoned man, who had passed the medical test and had worked for some time. His attack of paralysis followed a prolonged period of dissipation which left him in poor health and unable to withstand conditions which he might otherwise have weathered successfully. The record of only one death in the large number of men employed, and that not directly chargeable to conditions on the work, in a job which lasted for 10 months, is fairly satisfactory, as compared with other records.

The experience at the Colorado Siphon probably adds nothing new to what is known of the contributing causes and the treament of caisson disease. These have been fully discussed in recent papers presented to the Society or published in engineering journals.

California Shaft—Intake Structure.

The condition at the California shaft at the commencement of pneumatic work has already been described. The work remaining to be done at that side of the river was, first, the construction of a plug, at the same elevation as on the other side; second, arrangements for making the junction from the tunnel end and cutting through the shaft wall without loss of pressure; and, third, the construction of an intake structure.

The plug requires only brief mention. It was of reinforced concrete, 4 ft. thick, and 17 ft. in diameter; and was bonded and keyed to the shaft wall, as on the Arizona side.

Above this there was constructed a quarter turn in the shaft, to change the direction of flow of the water from vertical to horizontal. This was of concrete, and built on a center line radius of 8.5 ft. Above the quarter turn there was a reducer, 15 ft. long, from the shaft diameter of 17 ft. to the tunnel diameter of 14 ft.

The tunnel opening into the shaft was to be between Elevations 49 and 63. A vertical timber bulkhead, of two thicknesses of 12 by 12-in. timbers, bolted and keyed together, was built across the proposed

opening. The ends of the timbers were recessed into the concrete, and a flooring and roofing of 12 by 12-in. timbers placed. The space was filled with adobe. In this way, when the tunnel was cut through, it would open into a compartment entirely separated from the main shaft by a pressure-tight bulkhead, and a strong, water-tight joint could be made. The shaft outside of the bulkhead was filled with sand and water to Elevation 120.

During the construction of the tunnel the work on the intake structure was completed. This, together with the main check and wasteway, briefly described later, controls the flow of water through the upper portion of the main canal in Yuma Valley. As may be seen

BULKHEAD IN CALIFORNIA SHAFT

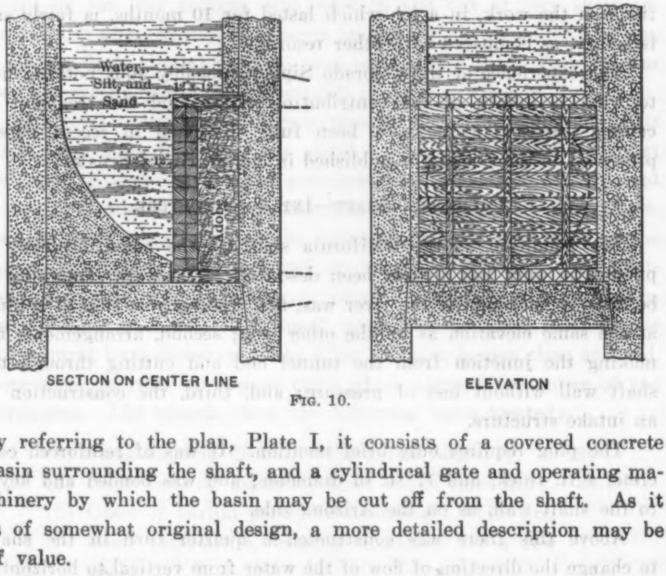

Fig. 10.

by referring to the plan, Plate I, it consists of a covered concrete basin surrounding the shaft, and a cylindrical gate and operating machinery by which the basin may be cut off from the shaft. As it is of somewhat original design, a more detailed description may be of value.

The main canal at this point is of trapezoidal section, having a bottom width of 80 ft. and a water depth of 7 ft. Warped retaining walls reduce this to a rectangular section 72 ft. wide and 7 ft. deep. From a line 15 ft. in front of the center line of the shaft, these walls, 11 ft. high, swing in, and around the shaft on curves of 36 ft. radius, compounded with curves of 17 ft. radius. At the rear of the shaft,

where these walls meet, and at points 120° from it, are constructed three piers, enclosing the guides for the cylinder gate. The floor of the basin is 1 ft. thick, with the top at Elevation 125, which is also the elevation of the canal bottom. The flow of water is directly down into the shaft, there being no obstruction except the guide piers. The whole basin is roofed over with a reinforced concrete girder floor, which is on a level with the top of the canal banks. On this floor is built the operating tower, into which the gate is drawn when the siphon is in operation, and which carries the operating machinery.

The gate has been described as a "bottomless tin can", set over the top of the shaft; it is 8 ft. high and 21 ft. in diameter. When it is down on the sill, its top is 1 ft. above the normal water level in the canal. The skin plate is $\frac{3}{8}$ in. thick, stiffened at the top and bottom by rings of 3 by $3\frac{1}{2}$ by $\frac{3}{8}$-in. angles, which in turn are supported by 3 by $3\frac{1}{2}$ by $\frac{7}{16}$-in. angles as chords. The whole is held rigidly to a circular shape by three radial stiffening or tie-brace trusses, at 120° from each other, connected to a cast-steel, three-winged center post. The gate-stems are secured to the gate at these three points on the circumference, as are also the guide-bearing castings.

There are two types of guides, designated *A* and *B*. The two Type *A* guides merely present a free bearing surface, which constrains the gate only in a radial direction. Type *B* guide, which is embedded in the heavy rear pier, encloses a portion of the bearing casting on the gate, and thus prevents both radial and circumferential motion. All three guides are single castings, 19 ft. 5 in. long, the lower 2 ft. being embedded in the foundation. They are anchored in the concrete piers throughout their length, and are fixed at the top by a triangular lattice girder frame which is embedded within the girders of the operating-tower floor. The guides and bearings are of cast iron, with machined wearing faces.

The circular cast-iron sill on which the gate rests is shown in section with the gate on Plate II. It is made in six sections, bolted together, and anchored in the concrete. It is bolted to the guides at the three points of contact. In placing the sill, the shaft was trimmed out roughly to form a bed, and the sill was brought to grade with iron shims, and grouted in place.

As previously stated, the cover of the basin is a slab and girder floor. It is surrounded on all sides with a 2-in. iron-pipe railing. Above it is the operating tower, of cylindrical form, 8 ft. $8\frac{3}{4}$ in. high.

which carries the gate-stand and operating machinery, and also forms a sleeve into which the gate may be drawn. The three gate-stands, on two shafts at right angles to each other, are operated through a gear drive by a 3-h.p. continuous-current motor. The gate weighs about 8 tons, and in ordinary operation is raised and lowered at the rate of about 2 ft. per min. The tower is accessible from the floor of the structure by a concrete stairway. Four cast-iron lamp-posts on concrete pedestals are placed around the structure. One of the main traveled roads of the Yuma Indian Reservation passes around the end of the canal at this point.

The construction of the intake was carried on with the same plant as that used in building the shaft. The foundations were excavated by Fresno scrapers and by hand. The foundation and floor were reinforced with old rails. The proportions of the concrete for the foundations were 1 : 3 : 6, and for the remainder of the structure, 1 : 2 : 4, granite screenings and sand being used for the finer material. The sand and stone were shoveled directly from the stock platform into the measuring hopper of the mixer; and the concrete was dumped into a 1-cu. yd. tip-bucket and conveyed to the forms by the derrick. Steam for the mixer and derrick was furnished by a 30-h.p., vertical, tubular, wood-fired boiler. The face forms for the warped walls were built on the ground in one section, 11 by 20 ft., of 1 by 6-in. tongued and grooved lumber, with studs about 3 ft. apart. They were lifted and carried to place by the derrick, and sprung to line and braced. Cut-off walls were carried 4 ft. into the ground, at the ends of the walls and at the edge of the floor.

The intake was completed in February. No additional work was necessary at the California shaft, except to remove the water and sand filling, and the temporary wooden bulkhead, described previously, and to make the connection with the tunnel.

Fig. 11 shows the placing of the cylinder gate on the shaft, and Fig. 12 shows the completed structure before water was turned into the main canal.

Outlet Structure.

The outlet structure is of much simpler design, there being no control of the flow at this point. The construction, however, was more difficult, owing to the topography, the want of space, interference with the tunnel construction and the plant, and the rise in ground-

water at the high stage of the river. The ground surrounding the Arizona shaft and for some distance from the river, is high and irregular in contour. The construction plant was grouped around the shaft in a basin at Elevation 147, which is 24 ft. above the bottom grade of the canal. The problem was to construct the retaining walls without interfering with the operation of the compressors, mixer, hoist, and boiler plant. The diagram, Fig. 14, showing the layout around the shaft and the outlet, will make clear the method of construction, which was to build the walls and foundation in a trench, the core being removed later.

The east wall was built in two sections, numbered I and II on Fig. 14. Each section was about 30 ft. long and 15 ft. wide. The bottom of the foundation grade was at Elevation 116.5 in I and at 118.5 in II. Sheeting, of 2 by 12-in. planks 20 ft. long, was driven as the excavation proceeded, with 6 by 8-in. rangers and cross-braces in horizontal bents about 5 ft. from center to center. Ground-water was encountered at Elevation 120; the soil was soft sand and tended toward quicksand below ground-water level. A small steam pump set in a sump at one end of the trench kept it dry. At Elevation 127 a second set of sheet-piling was driven. When subgrade was reached, a layer of crushed rock was placed, to provide drainageway and prevent the bleeding out of the sand under the wall by the flow of the ground-water. The reinforcing steel for the wall and foundation was then thoroughly wired in place, and the foundation concrete placed. Forms for the wall were built in 5-ft. lifts, the trench bracing being removed and back-fill being placed as the wall was carried up. The track from the mixer to the shaft was carried over the trench on stringers, and the track to the dump was moved to the other side of the shaft. The concrete for the wall was chuted directly from the mixer to the forms.

The full length of Trench III was opened at once; the trench bracing and sheeting was similar to that in the others. At this time the spring floods of the river had started, and the accompanying rise in ground-water was more than 5 ft. It was found impossible to carry the subgrade as low as on the opposite wall, as the upward flow of water through the ground grew too large in volume to handle conveniently and threatened to "blow up" the soil under the ends of the sheeting. The subgrade, therefore, was made at Elevation 119,

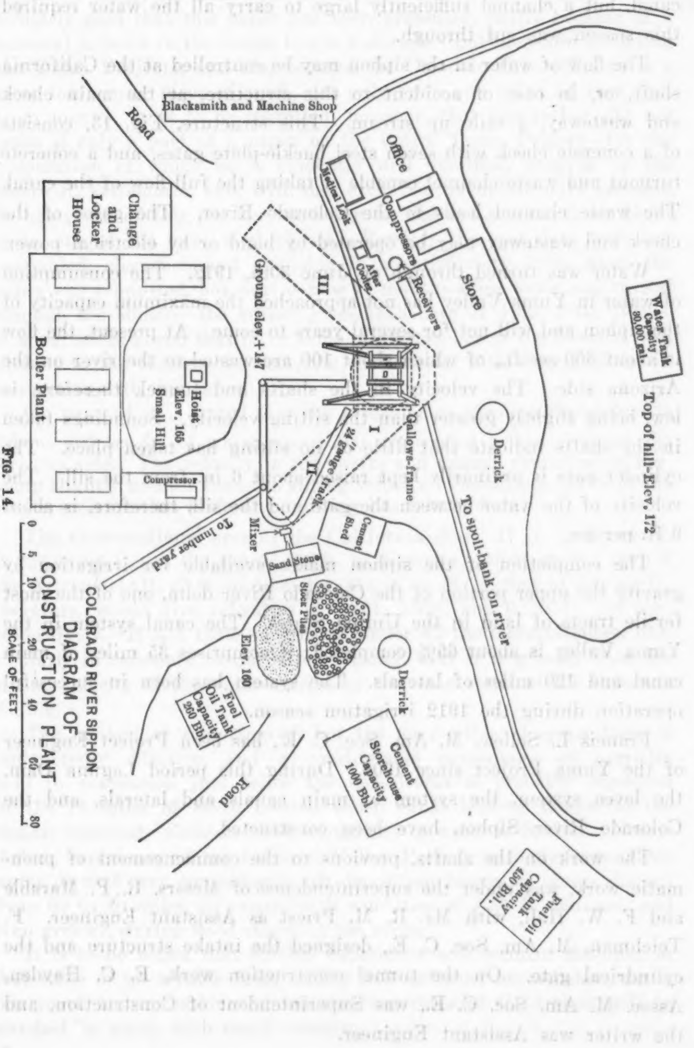
and the foundation and walls were constructed as on the opposite side. As this subgrade is 4 ft. below the flow line of the canal, there is small likelihood that the water will scour to this depth. The flow of water through the siphon during this irrigating season has been only a small portion of the full capacity of the structure, and the velocity at the outlet has been relatively low. During the present winter season a concrete floor will be placed on the canal bottom at the outlet, protecting the foundations against scour at full flow.

The retaining walls are designed to resist an uplift due to a 6-ft. head of water, combined with a pressure on the back of wall due to an angle of repose of 17° 30′. The wall is 3 ft. thick at the base, and has a batter on the back of 1 in 12. The top is at Elevation 141. From the top of the wall the ground slopes back at a 2: 1 slope to Elevation 150. There is a berm 16 ft. wide for a road, and back of it a gravel and sand hill.

The work remaining to be done from the Arizona shaft was the removal of the tunnel floor, the lock, and the bulkhead, the cleaning up of the tunnel, the removal of the cage-guides, gallows frame, and cribbing from the shaft, and the construction of a quarter-turn gooseneck at the bottom of the shaft, enlarging the diameter of the tunnel to that of the shaft.

The shape and dimensions of the gooseneck are shown on Plate II. The changes in direction and velocity are easy, and there will probably be no great loss of head at full capacity. Circular forms were built on radial lines, and the lagging was brought up and the concrete placed in 3-ft. or 4-ft. lifts. The last work done before the running of water was the removal of these forms.

On the ground between the retaining walls, where the canal leaves the shaft, there were the hoist, boiler plant, one small compressor, and the change room. The hoist was removed, and a small hoist was set temporarily on the opposite side of the shaft. The boiler plant was needed only for the derrick and hoist, as at this time the pressure was being lowered in the tunnel, and the compressors had stopped. The office was removed, and a temporary installation of three boilers was made at this point, and everything was removed from the canal right of way. The excavation of the canal had been proceeding from the other end of the heavy cut section with Fresnos and wheelers, and the short piece remaining between the completed portion and the shaft



COLORADO RIVER SIPHON
DIAGRAM OF
CONSTRUCTION PLANT

FIG. 14.

was now removed. Owing to the rise in ground-water it was impossible to excavate lower than 2 ft. above the final bottom grade of the canal, but a channel sufficiently large to carry all the water required this season was cut through.

The flow of water in the siphon may be controlled at the California shaft, or, in case of accident to this structure, at the main check and wasteway, ½ mile up stream. This structure, Fig. 13, consists of a concrete check with seven steel buckle-plate gates, and a concrete turnout and waste channel capable of taking the full flow of the canal. The waste channel leads to the Colorado River. The gates of the check and wasteway may be operated by hand or by electrical power.

Water was turned through on June 30th, 1912. The consumption of water in Yuma Valley has not approached the maximum capacity of the siphon and will not for several years to come. At present, the flow is about 300 sec-ft., of which about 100 are wasted to the river on the Arizona side. The velocity in the shafts and tunnel, therefore, is low, being slightly greater than the silting velocity. Soundings taken in the shafts indicate that little or no silting has taken place. The cylinder gate is ordinarily kept raised about 6 in. from the sill. The velocity of the water between the gate and the sill, therefore, is about 9 ft. per sec.

The completion of the siphon makes available for irrigation by gravity the upper portion of the Colorado River delta, one of the most fertile tracts of land in the United States. The canal system in the Yuma Valley is about 65% completed; it comprises 35 miles of main canal and 120 miles of laterals. The system has been in successful operation during the 1912 irrigation season.

Francis L. Sellew, M. Am. Soc. C. E., has been Project Engineer of the Yuma Project since 1906. During this period Laguna Dam, the levee system, the system of main canals and laterals, and the Colorado River Siphon have been constructed.

The work on the shafts, previous to the commencement of pneumatic work, was under the superintendence of Messrs. R. P. Marable and F. W. Hall, with Mr. R. M. Priest as Assistant Engineer. F. Teichman, M. Am. Soc. C. E., designed the intake structure and the cylindrical gate. On the tunnel construction work, E. C. Hayden, Assoc. M. Am. Soc. C. E., was Superintendent of Construction, and the writer was Assistant Engineer.

DISCUSSION

H. T. Cory, M. Am. Soc. C. E. (by letter).—The writer is particularly glad that this paper has been presented, partly because of a personal interest in the entire Lower Colorado (and therefore including the Yuma Project), and also because the Colorado River Siphon is a most interesting piece of work, not only from one point of view, but from many. It is to be regretted, however, that the author did not make it only a part of a paper on the entire Yuma Project—for the preparation of which he is evidently well qualified, judging by the clear-cut, systematic, and, with one exception, comprehensive account, he has given of this portion—and that he did not say anything about costs, one of the most vital phases. Possibly the cost data were not assembled, classified, and available in a satisfactory form when the paper was submitted, but as it is now 11 months since water was turned through the siphon—the author gives such date as June 30th, 1912—it is earnestly hoped that he or some other member of the Service, will present to the Society the complete cost sheets, with distributions, in connection with this paper. Mr. Cory.

On page 34 it is stated that the present flow through the siphon is "about 300 sec-ft., of which about 100 are wasted to the river on the Arizona side. The velocity in the shafts and tunnel, therefore, is low, being slightly greater than the silting velocity. Soundings taken in the shafts indicate that little or no silting has taken place."

The cross-sectional area of the California shaft, 17 ft. in diameter, is 226.98 sq. ft.; of the tunnel, 14 ft. in diameter, 153.94 sq. ft.; and of the Arizona shaft, 23 ft. in diameter, 415.48 sq. ft. A flow of 300 sec-ft., therefore, would give velocities of 1.321, 1.936, and 0.722 ft. per sec., respectively. It is a little surprising, under all the circumstances, particularly in reference to the latter velocity, that it is greater than the silting velocity of the water carried by the main canal at the Colorado Siding.

The method of removing all but the finer silt at Laguna Dam is undoubtedly effective, and a considerable percentage of particles held in suspension just below the head-works is probably deposited in the 14 miles of 80-ft. bottom width canal leading thence to the siphon, especially while so small a quantity of water is flowing. Nevertheless, experience in the Imperial Valley Project, with the same river water, is that very considerable silt deposition occurs at points distant from 60 to 80 miles, in canals with velocities of 1.35 ft. per sec., and even greater, during flood stages in the river.

It is to be hoped that further experience will confirm the opinion that little or no trouble from silting will develop; nevertheless, for a few years, the operation and maintenance costs of the siphon will be watched by many with much interest.

Mr. Cory. The writer also hopes that the discussion will bring out the considerations and data which caused the adoption of the various diameters of the Arizona shaft, the tunnel, and the California shaft, and particularly as to the weight assigned, in so doing, to the silt problem.

Mr. Schobinger. GEORGE SCHOBINGER, ASSOC. M. AM. SOC. C. E. (by letter).—The danger of the siphon silting up is hardly as imminent as Mr. Cory fears. Although it was operated throughout the irrigation season of 1912 with a flow rarely exceeding more than 300 sec-ft., no diminution in efficiency was noted. During the season of 1913 the flow has sometimes been as high as 600 sec-ft. with similarly satisfactory results.

Fig. 15 shows the rating curve for present operating conditions. As noted thereon, the head available may vary under ordinary circum-

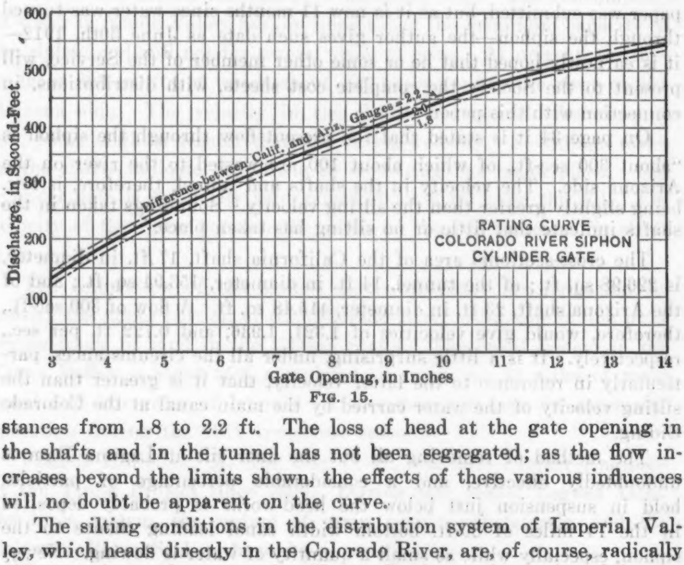


FIG. 15.

stances from 1.8 to 2.2 ft. The loss of head at the gate opening in the shafts and in the tunnel has not been segregated; as the flow increases beyond the limits shown, the effects of these various influences will no doubt be apparent on the curve.

The silting conditions in the distribution system of Imperial Valley, which heads directly in the Colorado River, are, of course, radically different from those on the Yuma Project, where the sluiceway settling basin of Laguna Dam serves efficiently to eliminate much of the silt and heavier sands, a result which was anticipated in the design of the dam. The results of a series of tests conducted by the writer indicate that from 30 to 60% of the silt carried by the river is dropped before the water enters the canal, and that more than 95% of the silt in the canal water below the head-gates is still in the water after it has flowed through 15 miles of canal at low velocity and

through the Colorado River Siphon. The velocity in the Arizona shaft is three times as great as that in the sluiceway at Laguna Dam, and therefore it is perfectly evident that a large proportion of the silt which might be deposited at these low velocities has been taken out. Mr. Schobinger.

However, even if these conditions were not so, and the unexpurgated waters of the Colorado flowed through the siphon, the writer is of the opinion that the method of operation would obviate any serious inconvenience. At the end of each week the water is shut off at the head-gates, and the canals are allowed to drain. When the water is again turned in, the head available to push it through the siphon may be as much as 9 ft., and this would effectually flush out any light deposit of the previous week.

The writer has recently taken soundings which indicate that there need be no apprehension as to the loss of usefulness of this structure due to silting.

It is doubtful whether a general article on the Yuma Project will be written in the immediate future. Laguna Dam, both in design and construction, has been described very completely by E. D. Vincent, M. Am. Soc. C. E., Resident Engineer,* and the levee work and bank protection by Mr. Sellew.† The Colorado River Siphon has been covered in the present paper, and in an article by Mr. Sellew.‡ Until the remaining important features on the Project are under way, it is not probable that a general article on the subject will be forthcoming.

The writer regrets that there has been no discussion on this paper by engineers familiar with pneumatic tunnel work.

TRANSACTIONS

Paper No. 1282

THE PHILOSOPHY OF ENGINEERING.*

By Maurice G. Parsons, Jun. Am. Soc. C. E.

With Discussion by Messrs. Lewis M. Haupt, Charles Kirby Fox, A. H. Markwart, Morgan Cilley, and Maurice G. Parsons.

Introduction.

Notwithstanding that engineering structures have but recently come to be designed with precision, and that machinery as we know it to-day is a development of the past century, some of the greatest engineering feats were performed almost before history began. The Chinese wall, the Indian temples, the sphinx—the seven wonders of the world—will always compel our attention and baffle our imagination. In truth, the ancients were builders of no mean structures, but, except to some extent in irrigation, their real engineering ends there. They were not producers of economic necessities as we are to-day, but confined themselves to the erection of monuments, as such.

Later, during the Roman era, the need of political security, public utilities, and the spirit of commercialism came to be of more moment than monarchical whim, and resulted in the construction of highways, aqueducts, and sewers, which, again, command our admiration and respect, the more deservedly because they were for so long unsurpassed. Furthermore, it is remarkable that the next achievement, the reclamation work in Holland, is not overshadowed by an undertaking conforming more closely to these precedents, the fundamental cause for such a departure doubtless being economic necessity.

* Presented at the meeting of June 4th, 1913.

All this time the engineer was, primarily, a builder without special training—with nothing but his judgment and common sense as guides. It remained for the Renaissance, with the steam engine, to produce the mechanic and the technical man busied with the construction of works of public utility, and for the present day to evolve what may be called the new engineer: the man of commerce, industry, business, who makes engineering a means rather than an end—the man of affairs.

Henceforth, managers and business men will more and more be chosen from among those engineers who can go back of stresses to the money side of things; and bankers are already relying on engineers to decide the advisability of investments, the kind and magnitude of structures, the operating and financial programme. For the engineer who can go still farther back—back of the dollar, to the public good—there opens up the vast field of government administration and policy forming—the field of the engineering economist—for government, particularly of municipalities, is in large measure of an engineering business nature. This is illustrated by appraisement work, especially, as is frequently the case, if it be in behalf of a political organization, where the appraiser must decide such questions as fair profit, what to do about franchise value, whether expenditures were justifiable, what class of service is adequate, and whether to insist on extending the right of eminent domain to public utility corporations.

Considering the opportunities newly presenting themselves to the engineer, there seem to be certain professional duties which we must discharge before we may walk worthy of the calling wherewith we are called, two of these being the obligations of contributing to education (of both the public and the Profession) and of applying newly established principles.

There should be no foundation, no possibility, for a remark that the engineer should be limited by the bounds of stresses and dimensions, and not stroll over into financiering and managing. Rather, it should be a matter of common report that the engineer, seeking the truth (as he must) stands not on the shows of things but on things themselves, that he, being closely related to all industrial adventures, must of necessity be familiar with questions governing their inception and their *modus operandi*. Over and above more generally establishing the engineer's fitness to sit in councils—literally based on this capability—is a higher duty, which will become more and more clearly

defined. This is the duty of reconciling business and the people, of being a peacemaker between those who produce our economic goods and those who consume them at what seems too high a cost. Many of the differences between capital and labor arise solely from misunderstandings, ill-selected points of view, and limited knowledge: to know all is to forgive all. There are a fortunate few who, in managing and evaluating, have opportunity to establish amicable relations between seller and buyer. There is a much greater number who can accomplish somewhat the same result by participating in professional discussions, local public meetings, and consultations of boards of directors, to the extent of explaining the complexities of modern sociology and commercialism.

To the end that members of the Profession may the more ably carry on this great work of public education, they should endeavor to educate one another by systematic and thorough interchange of ideas on such subjects as business and banking, human nature and government, rather than continue to leave each to strive as best each may, obtaining by individual effort a fragmentary knowledge thereof. To illustrate this point, it may not be out of place to call attention to the confusion existing in regard to "Going Value," "Water," and "Development Expenses," as brought out in the discussion of the paper by Henry Earle Riggs, M. Am. Soc. C. E., entitled "The Valuation of Public Service Property,"* and to the fact that no one seems to know just what to do with "discount on bonds," a question discussed in parts of that paper. Such a principle that good enough is best, that "one may get too much for one's money"† should be so established among engineers as to be applied habitually. Another example of the evil results of having centered perhaps too large a proportion of attention, as a Profession, on technical details, and too small a proportion on the working principles of big things, is the unfortunate statement that "it would be, not only bad engineering, but bad business,† as if engineering and business were not, fundamentally, one and the same thing—bad engineering can be nothing else than bad business.

The second large professional duty, that of taking the initiative of applying principles, is readily suggested by two statements‡ on

engineering and economics in the discussion on Mr. Riggs' paper, one to the effect that engineering occupies a part of the subject of economics, and the other that "the engineer is essentially an economist." Without quibbling over the question whether economics is a part of engineering or engineering a part of economics, it may be stated axiomatically that modern engineering is based, not on personal ambition, national pride, worship of stone, or military necessity, but on economics. A real political economist acts on this theory. Financiers and statesmen always have been such, and engineers now are. More than this, Courts at times require them to establish their theory. Our present social and commercial structure places on the engineer the obligation of taking the lead. The engineering economist, the new engineer, must guide the banker as well as build and operate his physical plants; he must act as mediator and policy former in questions of state; he must launch out into the deep. To quote from the Presidential Address of John A. Ockerson,* Past-President, Am. Soc. C. E.:

"There seems also to be a disposition to avoid participation in the discussion of public questions, even when closely related to the work of the Profession. When Congressional Committees call on the Society for advice with regard to pending legislation, involving questions relating to engineering, it would seem to be a proper function of the Society to render such aid as may be practicable.

"In fact, it might be well, under proper conditions, to go even farther, and use the influence the Society may have to mould public opinion along lines free from local or political bias, when our public works are the subject of discussion.

* * * * * * *

"As a matter of fact, the Society is already regarded by the public so highly that its members are looked on with special favor by the Courts when expert testimony is required, by the Government when seeking for capable men for service on public works, and by municipalities where men of integrity and ability are looked for to fill positions of trust relating to the engineering side of city government.

"In a speech at the Society House recently a leading politician of New York announced that they have come to realize that the interests of the city are best served by appointing engineers to fill the important offices which have charge of the physical welfare of the city in general.

"This is true of many of our cities, and the Profession is steadily growing in public favor; loyalty to the Society on the part of all its

---

members wherever they may be located will greatly stimulate this growth."

Led by his interest in this newly conceived field of professional activity, the writer begs to present some reflections on sociology, commercialism, and the theory of engineering expenditures.

Social Structure.

As a foundation for the ideal conduct of life, there has been formulated the proposition that the greatest good possible should be striven for (whether this eliminates individual, genus, or species); that the common weal is the proper goal; and that, not only one generation or age is to be considered, but that all future generations and ages should have a proper weight in the final sum total of welfare. That is to say, all life has its standing in court, be it plant or animal, present or future.

To the end that man should have his fair share of this world's goods, there were organized the primitive protective leagues which have developed into our modern governments, one of the highest functions of which is modern communistic protection, the exercise of police power, defined as:

"That power which inheres in legislation to make and enforce all manner of reasonable regulations and laws to preserve the peace, order, and safety of society, and to prescribe the mode and manner in which every one may so use and enjoy that which is his own as not to preclude a corresponding use and enjoyment of their own by others."

To-day, man no longer needs protection against his original savage enemies. They are conquered, and he now turns his attention to other pursuits, foremost and basic of which is the production and distribution of more economic necessities and luxuries, the direction of "the great sources of power in Nature for the use and convenience of man." As mutual protection undoubtedly influenced the form of early government, we have, to-day, inevitably, a business form of government. Business is the chief occupation of the average individual. We live in a commercial age. Business and government to-day are inseparable, but, as originally, human welfare (and not government or business) is the *causa causans* of government and business.

This point deserves emphasis. The good of the people is the primary object of government and business, "business" prosperity being a sec-

ondary and incidental end, or, more correctly, simply a means to a richer and fuller life. The long-time security of investments, ultimate stability of government, and eventual greatest common weal of man are inextricably interdependent. Whatever truly furthers the one furthers all, and whatever threatens one does, in the long run, threaten all.

As the creature and creator, the servant and master, of this triple alliance (that of people, government, and business) stands the engineer. An abhorrer of greed, a seeker of the truth, a designer, builder, and operator of public utilities, he is at once: the people's protector, for the innocent investor can know at first hand nothing as to the security of his savings; the business leader, for a going concern is an engineering product; the advisor to governments, for business rightly has a voice in government, and many governments now embark in business; and the mediator in disputes arising between people, business, and government.

The actual state of affairs is a long way from that just outlined as the one to be striven for, albeit the general trend is toward, rather than away from, perfection: though not as yet, but some day, the lion will lie down with the lamb.

People collectively and individually contribute to imperfections; lacking knowledge of what constitutes the supreme good, man has builded on the philosophy of the good of man. Individually, we in all cases (to a greater or lesser degree) place the good of self first; one's self is paramount to one's fellows; altruism, the spirit of service, comes second. Collectively, we at times make unwarranted expenditures of money; we dissipate the property of posterity with a spirit of absolute indifference to the future; we war among ourselves, one institution against another.

Government, lacking the one-time incentive to the protection of the governed from external enemies, has given a part of its energy to protection from internal enemies. We now have vested interests and special privileges. Our economic ills of to-day, such as high tariff, monopoly caprice, concentration of wealth—and so on down a painful and familiar list—are laid at the door of government, apparently without realization that in America the People is the Government. To have nationally, we need individually, a more awakened spirit, so that our business form of government will the sooner be

purged of its ills through the application of a governmental and commercial unified policy favorable to all interests.

Business, blinded by the dust of extensiveness, has at times failed to perceive its primary fundamental object, and has been guided by its secondary fundamental object: the welfare of the people has been incidental to the apparent welfare of business. With the cessation of territorial annexation and colonization is coming the more clear-sighted and deliberate period of intensiveness, so that already the short-time balance of accounts gives way to the long-time reckoning: corporations are, happily, changing their attitude—they are beginning to see farther than their noses, and consequently are considering the effect their policies have on the ultimate stability of business through their effects on virility.

Engineering Expenditures.

As engineering enters so intimately into every phase of human life, and as every engineering proposition must needs be financed, the writer is much interested in the general subject of engineering expenditures. He realizes that:

1.—In the work-a-day world, the philosophy of the good of all life is entirely too abstract and general—it is a sort of sacred standard. There is needed a more concrete and particular criterion—a field tape, as it were—in determining whether an object be worthy, which test must necessarily be, "Will it pay? How much money will it make?" The sum total of all our investments, in order that we may not deplete what capital has been handed down to us, must net at least zero; and, if we are to bequeath as much property *per capita* as we received, this sum total must net a positive quantity.

2.—By happy combinations of capital and labor we are enabled to add to the world's wealth, its increase being measured by the profitableness of the venture which depends on the acumen displayed in selecting a field, erecting a plant, and managing the business as a whole. Each of these three phases (selection, construction, operation) is becoming, through our division of labor, with its consequent concentration and specialization of effort, multiplication of possibilities, and increase in size of units, more and more difficult of proper solution.

3.—The successful engineer is the one who grasps the principle that engineering is business—that good engineering is good business—and solves the questions, "How much?" and "Will it pay?" with capable engineering business judgment. In any engineering business possibility, the engineer, before passing on the security of an investment, must know the balance between gross annual expenditures and gross annual receipts; the difference giving the net annual income, positive or negative as the case may be, but always positive except when people are in business for their health or amusement. This rigid requirement, that an undertaking must be commercially feasible, strangles the industrial application of many scientific possibilities.

Notwithstanding that an analysis of profit, to be complete, must comprise an enumeration of the factors of gross income on the one hand and of gross expenditures on the other; and, further, notwithstanding that receipts and expenses are generally interdependent, this paper deals but little with the former. It is hoped that some one will present a paper on the elements entering into gross income.

In brief, total income is the product of unit prices and the number of units sold, both fluctuating according to the law of supply and demand, or the law of monopoly distribution—in any event according to the law of variation of returns.

The factors of total annual cost—to deal with this side at somewhat greater length—are interest on first cost (unmistakably including development cost); depreciation or sinking fund; the creation of a reserve for extensions, betterments, and unforeseen contingencies; outlays for raw material and supplies; maintenance and repairs; wages, salaries, and royalties; rent, taxes, and insurance. These factors, intricate within themselves, are, in addition, involved in a complex interdependency. To illustrate:

In designing an important bridge, considerable attention may be given to the question of economic dimensions, first cost alone being considered. It is then to be remembered that first cost and maintenance are bound together, indifferent material and workmanship necessitating heavy up-keep charges. Moreover, precisely how fast depreciation should be allowed to take place and exactly to what extent it should be checked by repairs, is only one of the multifarious issues the engineer must determine. To wander back, for a moment, to receipts, the rate of exploitation of an exhaustible resource is of fundamental

importance in its bearing on first cost: Should a plant be installed capable of using all available raw material in ten years, or a thousand? As a final example, illustrative of the influence any factor of the cost of production has on every other factor, and of the weight each has in the balance between income and outgo, we may consider the rate of exploitation of a perpetual resource; more specifically, we may ponder on the height of dam in any water-supply problem as it enters into questions of cost and useful and wasted draft.

These considerations bring us to the general question of the best size of engineering expenditures ("What is the best height of dam within the limits of height giving rise to a proper return on cost," and "What is the best rate of exploitation of a limited quantity of ore," being two examples), on which question the following theory is formulated:

Of all possible arrangements of all expenditures, that one is best which secures the maximum present worth of ultimate total incomes. This statement applies to an imaginative case dealing with the sum total of all expenditures and receipts. That is to say, it does not mean that if $10 000 000 spent on a railroad will net a final profit worth now $15 000 000, whereas $20 000 000 spent will yield a sum worth now $26 000 000, then the latter amount is the better to invest, unless the second $10 000 000 would be idle or be put in an enterprise which would ultimately return a sum the present worth of which is less than $11 000 000. To generalize this limitation: all possible opportunities for investment should be considered in the light of all the revenues they would yield, and those investments should be made which would secure the maximum total of the present worths of all incomes, more or less capital being put here or there to procure this result. The example of the dam may further clarify matters: From the point of view of the dam investment alone, we want the highest rate of interest; but it may be possible, on the one hand, to put elsewhere part of the money available for this purpose at a yet higher rate, in which event we would choose some other than the highest rate obtainable from the dam; on the other hand, a dam larger than that securing the highest rate on the dam cost might yield more returns on the surplus investment than that same money could earn elsewhere, whereupon we would choose, again, some other than the highest rate obtainable from the dam. In other words, we would put our money where it would do the most good.

Time is another element included in the general statement, as may be seen from the following example: If to exhaust a body of ore this year would net 0.0872x$ while to save that ore for use during the fiftieth year from now would net more than $$x$ (interest being taken at 5%), it would be good business thus to delay, $0.0872 being the present worth of $1 fifty years hence. Or, again, policy would dictate delaying 50 years if then more than 11.4674y$ and now only $$y$ would be produced (interest being at 5%, $11.4674 is the value of $1, at annual compound interest, fifty years hence). Taking this same body of ore, we could mine it all in, say, one or ten years. If (disregarding other places to put money), beginning now, we mined it in one year at a net profit of $$z$, and by mining it during 10 years at a uniform profit we obtained an annual net profit greater than (1.62889 × 0.0795) $$z$, or approximately 0.1293z, it would be the part of wisdom to exploit at the slower rate. (Here interest has been taken at 5% per annum, $1.62889 is the amount of $1, at annual compound interest, ten years from now, and $0.0795 is the annual annuity required to accumulate $1 in ten years.) In other words, we would spend our money when, and at the rate at which, it would do the most good.

To repeat: The ideal engineering expenditures would secure the maximum present worths of net income.

To obtain this ideal distribution of financial resources among all departments of industry would necessitate two steps. Of these the first would be a set of differential investigations (for each and every commercial enterprise), enquiring into the relation between expenses and revenue, several trial solutions being necessary to determine the results of a variation in the size of physical plant and of a postponement in initial development or subsequent improvement. These differential investigations having been made from time to time, and as new possibilities presented themselves, the results would be sent to a central clearing house where the second step, that of integration, would be taken. There the higher engineering would be performed—the financial decisions made—in the light of public policy, industrial and human welfare, and the results disclosed by the differential investigations. From a purely commercial point of view, effort would be put forth to secure such an extensity and intensity of industrial activities, by introducing changes here, allowing more money for construction or operation there, hastening exploitation in one place, and

conserving resources in another, as to secure constantly, under changing conditions, the maximum present worth of net incomes ultimately derivable from all business. The men who would thus fix the world budget should necessarily be broad and sympathetic, of absolute integrity, well schooled and experienced, and possessed of such a knowledge of the inwardness of things as to realize that he who would rule must be servant of all, and to base their apportionments on the proposition that, in the end, the labor and capital interests, the human and industrial interests, the interests of people, government, and business, are one.

In the commercial world we could stub along without a realizing sense of this underlying theory of engineering and business, of engineering expenditures. Indeed, we seem in cases to be absolutely uncognizant of the relation between business and people, or of the principle of compound interest. Some concerns muzzle the ox that treads out the corn, others fail to conserve resources, and others, contrariwise, are admittedly charitable. For the most part, however, our organizations fit into the system in a fairly satisfactory way, from the point of view both of the humanist and the commercialist. The secondary fundamental of business, that a concern must make money, is automatic in its application. If a business does not pay, it fails—the result is simple and unavoidable. We must get more money out of business, as a whole, than we put in (financial efficiency, so to speak, must be apparently greater than 1), and the only way to do this is to turn labor into capital by means of existing capital. Our machinery will never be completely self-acting. We, also, must work. In striking a balance between gross annual cost and gross annual income, there is, in all organizations, considered as a whole, a positive profit, except in early or bad years.

In the case of large and old companies, this profit is at times less than it should be by reason of unknown development costs. Nor is development cost the only factor of total cost sometimes neglected, depreciation being overlooked only less frequently than it; but, all in all, any going concern pays. If too many items are neglected, one way or another, it ceases to be a going concern.

Only by chance can the best arrangement of all factors of total cost be had: Proper maintenance is dependent on first cost, length of life, cost of repairs, and cost of reproduction; operating expenses

are subject to change without notice, because of improvements in the arts or fluctuations in supply prices or wages; accident frequently plays its part in the cost of the finished product. These and many other influences render the minimizing of costs a comparative matter requiring the best of engineering business judgment.

In the daily conflict of the commercial world, there is a strong temptation to overlook the theory of maximum present worths of net income (which, it may be noted, is at the bottom of conversation), to forget those generations yet to come, and to strike out, every fellow for himself and "the devil take the hindmost," in pursuit of maximum present returns.

This is due in some instances partly to selfishness, but, regardless of motive, there are always certain circumstances limiting the perfect adjustment of engineering expenditures. One of these is our lack of information of the future: we know not what a day may bring forth. Another is the fact that some people prefer to have their property within sight than to place it elsewhere more profitably. Again, many do not wish "to carry their eggs all in one basket," even though a single one promises less trouble and more gain. The fact that capital must occasionally completely develop or leave entirely untouched property considered as a legal entity, whether or not the maximum possible development is the most economical, whether or not a part of the required capital could be more profitably placed elsewhere, is still another circumstance limiting perfect adjustment of expenditures, as is also the requirement that certain funds be handled as a financial entity (be kept intact) even though a distribution of means between two or more projects would bring better results. Lack of funds is most common of all. The foregoing classes of limitations may be considered as special cases, and are unimportant in comparison with the general prevailing incomplete knowledge of present and future conditions and possibilities. The man with only a small amount to invest cannot make large outlays in search of the best opportunity, but must "hit a head when he sees it." Even those who handle large sums can, as a rule, be informed only in certain specialized fields of business, and cannot completely cover even those; and at best the heaviest bankers can know of only a few of all the places where they can make secure investments.

This absolute impossibility of sending all information to a central

clearing house, taken with the accompanying red tape, which would tie up large amounts in investigations, and in which human frailty would certainly become entangled, has given rise to local and national concerns; to a practical working engineering business organization composed of small and large units, apparently separate and distinct, but, in effect, part of a unified whole.

Small rule-of-thumb undertakings may require no engineer whatever, but the small banks and, as a rule, individuals controlling more than very moderate sums, retain engineers for advice or to design as per instructions the physical plants necessary in the every-day local affairs—such affairs as are assumed to be of a paying nature and require only limited capital.

As we get into fields of more and more importance, the engineer occupies an increasingly conspicuous position, an example of the transition from local to national engineering being given by the case where an energetic citizen makes a water-power filing, then has a preliminary investigation of possibilities made, the result of which may justify careful and detailed study by more experienced men, which study may in turn lead large financial interests to design, construct, and operate a hydro-electric plant. So we lead up: an idea, a local engineering study, a bond issue development. The local engineer handles the small work; big jobs must be done by those who can furnish the money.

There is thus seen the absolute necessity for a money trust—for a ring of men commanding tremendous amounts of capital (it may be the accumulated individual savings of a nation) furnished with accurate information as to the probable balances between expenses and incomes of large ventures, endowed with good judgment, and broad in philosophy, which ring can direct where money shall be spent, how much shall be spent, and who shall spend it. A money trust, a central authority, is an absolute necessity.

Certain abuses with which "money" is now charged are not necessary: The producer should not be underpaid while the consumer is overcharged—he is the same man, and on him rests "prosperity." Arbitrary decisions should not be made contrary to the revelations of scientific discoveries, with the object of momentarily swelling the private purse. No just cause can be found for dealing as we do now in shorts and longs—for selling what we have not got and buying what

we never expect to own. Nor can we excuse violent and sudden fluctuations in the value of stocks and bonds, with the accompanying panic or strong market, as the manipulator may desire, while the wheels of industry turn, unheeding, precisely the same. Furthermore, gain resulting from high prices and low wages should not be capitalized. "Water" is bad business. The management of investment securities with resulting transfers of certificates of ownership, which may be called financial engineering, is a necessary incidental of modern economic conditions and an entirely different thing from bull and bear skirmishes. Such things are in fact entirely foreign to industry, to good business, to sound enterprises. "Such things ought not to so be."

Conclusion.

Having passed through the eras of constructing temples, of erecting personal monuments, of cutting ourselves off from intercourse with other peoples, we stand to-day in the age of international commercialism, but not of commercialism at its height. Although the pendulum seems to be swinging back, although some sense again the raising of roses instead of dollars, we have only begun to see the vast field of engineering business. Commercialism, big business, is here to stay.

The application of the theory of engineering expenditures is possible only when bankers have a broad vision and a wide range of choice; they can invest money most profitably only when they know all possibilities. Economy of production and satisfaction of service are best obtained by large units, by monopolies. Competition, with its duplication of expenses, is uneconomical, and contrary to the principle of division of labor. We want one butcher, one baker, one candlestick maker. The best kind of a business is a well-managed big business. The day of little things has passed.

As each individual now has a voice in local and National government, so too each will come in time to have an actual direct share in small and in big business. Each will have some daily occupation (something to keep him busy with his immediate physical surroundings), together with securities (bonds, or shares of stock) issued by a large business concern. We will come in time to a common ownership of big business, over and above general possession of only personal effects, either by government ownership or by widespread indi-

vidual ownership of small amounts of stocks and bonds. In either event, because of the interdependency of business, government, and people, we will come—are coming—by means of enlightened self-interest, to a closer alliance between them. Enlightened self-interest is not anti-commercialism, it is pro-commercialism. The making of money is not incompatible with the making of men. Both processes will continue. Corporation publicity and the spirit of individual service are only the first feeble gasps of a new-born co-operation of business, government, and people.

DISCUSSION

Mr. Haupt.

LEWIS M. HAUPT, M. AM. SOC. C. E. (by letter).—Mr. Parsons' admirable paper is worthy of being read and known of all men, and especially by the members of the Profession whose duties make them pioneers in the development of the resources which the Creator has placed at their disposal.

The altruistic, fair-minded, open-handed spirit which permeates this "philosophy" is so fully in accord with the Golden Rule that, if it were realized and practiced by engineers in general, it would make them the dominant agency for the general uplift of humanity. The man who is in touch with Nature and correctly interprets her secrets is, of necessity, a lover of truth, and one to inspire confidence in his judgment and integrity.

It is true that a good engineer must be an economist; but economy is not always synonymous with business. "High finance" lives on credulity, fluctuations "on 'change," cupidity, patronage, and other elements, too often created by and sanctioned under the guise of law, and it is erroneously assumed that the more money put in circulation by appropriations from the public treasury, the greater the benefits, regardless of the results. It should not be forgotten, however, that the revenues are derived from the people as a whole, and are doled out to special interests employed by or under the control of the Government, whose main purpose is to serve the appointing power and hold on to the party patronage, so that the larger the appropriations the greater the power and the stronger the party. This policy of Government soon leads to despotism and profligacy, with resulting distrust and destitution, the remedy for which is to be found in an economic, judicious application of public monies to secure definite results on approved plans demonstrated by experience, and also on free and open competition, with right of appeal—in case of disagreement—to impartial arbiters, and not to the parties who frame the specifications and make themselves the final and sole authority. Such a policy has brought ruin to many honest contractors who have met with unforeseen and unexpected physical obstacles, or with ignorant inspectors.

The author has shown how "many-sided" the well-qualified engineer should be, not only in the various branches of his profession, but in the collateral ones of finance, legislation, organization, and business in general, and not merely an honest man skilled in the technique of his calling; yet how few there be who reach this standard.

If the engineer who knows what is required in the physical world with which he has to deal does not also assist and advise the Legal Profession or the legislator in the framing of laws authorizing and regulating transportation or municipal improvements, there is great

Mr. Haupt. danger of injury and injustice being done to the community; as, for instance, in the case of the disposal of the sewage of densely populated centers like New York or Chicago.

In the latter instance, the quantity of potable water required to render the sewage innocuous was carefully determined, per capita, and an open conduit was constructed, by legal authority and enactment, to discharge that required volume across the Chicago Divide into the Illinois and Mississippi Rivers—a quantity necessarily increasing with the density of population. Now, when it is found necessary to pass 10 000 cu. ft. per sec., to dilute the sewage sufficiently, the Government withholds its permission, leading to the inference that the residents along the route of the outflow must be content to use water contaminated by sewage, injurious to health, and which must increase in its percentage of albuminoids with time; or else, that the Sanitary District must find some other method of disposing of its refuse matter after expending millions in good faith and by approval of the Government. "Business and Government" are inseparable, but the latter should be liberal, not dominant; stable, not fickle; regulative rather than executive in the physical works and operations which may be safely and honestly administered by competitive corporations.

If, as stated, the "good of the people" were the primary object of Government, partisanship would soon disappear, and many of the evils accompanying politics would vanish. We cannot expect such a condition, however, under the *laissez faire* policy of keeping out of politics and letting the machine run itself, in the old ruts. It needs the engineer to prepare the way for a better standard, socially, morally, physically, and even spiritually. Then "every valley shall be exalted, and every mountain and hill shall be made low: and the crooked shall be made straight, and the rough places plain": and an highway shall be there, on which the wayfaring man may find occupation and repose.

Mr. Fox. CHARLES KIRBY FOX, ASSOC. M. AM. SOC. C. E. (by letter).—The writer has read this paper with much interest, and thinks that any papers or discussions which will tend to broaden the field of engineers should be encouraged.

The author's questions, "Will it pay" and "How much will it cost," reach the core.

Speaking of the old-time engineer, the author says: "All this time the engineer was, primarily, a builder without special training—with nothing but his judgment and common sense as guides." From old and new works and from plans which the writer has seen and heard about, he is inclined to think that these two items, with a liberal allowance of loyalty and "stick-to-it-ness," are the principal qualifications of an engineer. He cannot have judgment unless he has acquired a good education and has had extensive experience.

In connection with the author's general statements, it might be worth while to take into consideration the testimony given in the preface of Wait's "Law of Operations Preliminary to Construction in Engineering and Architecture": Mr. Fox.

"It is not the mere competency to design, draft, lay out, and superintend work that gives reputation to an engineer. This is work done by assistants who are comparatively unknown to the profession. The men who control and direct the work are men of broad ideas and business capacity, whom companies and proprietors expect will look after their business conservatively and hold their investments secure and profitable. This, it is contended, depends largely upon their business and legal training. Without this training graduate engineers find their many technical qualifications without weight in the estimation of their employers, and they feel it keenly when men with a general education are taken from the ranks of clerks and office help and are given direction of work as superintendents and managers wholly on account of their knowledge of the business policy which directs the financial operations and because they know from association and study how to decide ordinary questions of business and law."

Following along the lines of broader business policy for engineers, H. T. Cory, M. Am. Soc. C. E., recently presented before this Society a very interesting and instructive paper on "Irrigation and River Control in the Colorado River Delta."* He not only described the engineering features, but gave a complete financial and commercial summary of this important work. This is the first time the writer has seen this important part of a construction enterprise treated in this manner. It is now well known that the overhead charges, such as promotion, financing, discount and interest on bonds, general charges, etc., amount to from 50 to 100% of the cost of the construction items. Many papers are written on the technical side of engineering, but practically none on the business and financial side.

At one time it was considered unprofessional for an engineer to have anything to do with the contractors or actual construction. In other words, his work was confined to the survey, designs, and inspection. Now, there is hardly a contracting company which is not handled wholly or in part by engineers.

Engineering has been defined in many ways as "the art of making the dollar go the farthest," and "the art of directing the great sources of power in nature for the use and convenience of man." Why not combine these and define engineering as the art of directing the great sources of power in nature for the use and convenience of man in the most economical manner possible?

A. H. Markwart, Assoc. M. Am. Soc. C. E. (by letter).—This is a very thoughtful paper. The engineer is becoming more and more a necessary and important factor in the modern social and economic Mr. Markwart.

* *Transactions*, Am. Soc. C. E., Vol. LXXVI, p. 1204.

Mr. Markwart.

system, and such papers tend to bring out this point in a dignified and scholarly manner.

In this day, labor is of value and creates value, and the highest efficiency thereof is constantly sought to the end that there may be no economic loss. The use of labor and the expenditure of capital in an efficient manner is the function of the modern engineer. In remotely ancient times human life had but little value, and a Pyramid was conceived to satisfy a ruler's whim or furnish for him a monument by which to be known after he ceased to exist. Though it is true that the ancients constructed such monuments with considerable skill—and one wonders how and by what means they were carried out—there was no wealth created thereby, as we understand the term "wealth"—the result of human activity.

Modern engineering is the result of necessity, and offers a peaceable field for achievement. The construction of such a great work as the Panama Canal, for the benefit of humanity at large, calls forth one's unbounded admiration. The engineers on this undertaking have made a personal sacrifice. They have given time and attention to a work which isolates them for a long period, and acts to their personal disadvantage in many ways. The emolument received is small, and they are removed from their usual associates and haunts, causing them to be more or less forgotten; the gap made is soon closed. Truly there is much food for thought when one realizes the obligation of society to such fore-lopers.

The engineer of ancient days knew nothing of the science of engineering as it is now understood. His work was the result of experiment. If a wall 1 ft. thick was insufficiently strong and fell, one 2 ft. thick was provided in the next venture. Beware of the engineer of the present day who constructs his work in this manner. It is the tendency of the engineer to be, not a parasite, but a creator, and a creator with constructive and not destructive theories. Furthermore, by training, his impulses are those of the conservationist. Few engineers would knowingly waste the materials and resources at their disposal. These are tendencies in the right direction, and are fundamentally economic in theory.

Normally, the engineer has but little interest in public life or political activity. This seems peculiar when we reflect that all his training has been along a line which tends to produce the careful and logical thinker. He should be a factor in any progressive régime, whether political or commercial, as he is not hedged in by precedent or prejudice. Generally speaking, the engineer has a responsive and receptive mind on ordinary problems, and he seeks to be shown the truth.

The writer at this point would call attention to the apparently increasing demand on the engineer in the architectural problems of to-day.

It would seem that the architect is gradually and voluntarily giving up his place as master builder. He does not fill the same office as did Michael Angelo, who was in turn, sculptor, painter, architect, engineer, and poet. On the contrary, the modern architect does not allow himself to qualify in this broader field of art; he assumes his most important work to be along esthetic lines alone. He is more concerned about the exterior appearance of his building than about any other feature. The façade, color scheme, and floor plan seem to hold the major part of his attention. Whether the construction of the proposed building will be a good commercial proposition is of no concern to the architect; rarely does he make a logical and convincing analysis of conditions to be met or problems to be solved. This is not a criticism, but a statement of a condition. Such matters as the financial report, the economic design, and the execution of the scheme are frequently left to the engineer. This is in support of the general idea advanced by Mr. Parsons, and is a confirmation of the opinion that the engineer is entering a broader field of activity. Mr. Markwart.

There is at present a movement on the part of engineers to develop a code of ethics. This should be encouraged and fostered. The architect has his code of ethics, and, generally speaking, it is a recognized and established standard for the profession, even in the eyes of the layman. All such codes have, as a component part, a schedule of fees, and though, on the face of things, this may appear to be mercenary, there is no doubt that there is considerable necessity for such a feature. The engineer should be adequately compensated, the compensation being measured in terms of the service rendered. A manifestly low price or insufficient compensation is an argument for a poor article or an inadequate service. A proper compensation must needs result in a better moral standard, and any code of ethics should include a schedule of prices, to bring this about.

Mr. Parsons has mentioned the ever-increasing demand for engineers in the various political, social, and commercial fields. It is becoming more and more the function of the engineer to act as adviser in actions or disputes between labor and capital; he is becoming the scientific purchasing or selling agent for large corporations; he assists in the valuation of property, for sale or rate-fixing purposes, and he frequently takes up sociological problems of considerable moment.

Engineering, from a broad viewpoint, requires a large supply of common sense, executive ability, and action. Our colleges should take this into consideration in their teachings, together with the question of moral training, to the end that to be an engineer is to be one who can be relied on to operate successfully under a high moral standard, so that his opinion and advice will be sought when other sources fail.

Mr. Markwart.

It has been said that the engineer frequently looks after his client's financial interests better than his own. There is probably considerable truth in this remark, and such a condition is inconsistent when we consider the broad responsibility of the modern engineer. This must be avoided, for there is something in the theory that personal financial prosperity is to some degree a measure of one's success. Prosperity, to some degree, promotes higher ideals, and, after all, the higher ideal is that which should be attained in all walks of life.

The old theory that a business should charge all that the traffic will bear is false, and other advanced and broader theories are taking its place. Good service is now, and will continue to be, considered as that which is to be rendered. Competition of service will in the future be the spur which actuates opposing concerns. This principle is essentially with us and in operation. From now on, a reduction in price is not necessarily going to obtain the business. Superior and improved service will have to be rendered. The "Philosophy of Engineering" very clearly brings out this phase of modern business.

It is only a question of time, in corporation activities, when many mooted points will be settled, and very probably by the engineer. For instance, what consideration should be given in the case of free rights of way as regards rate-fixing purposes? Should the public be a partner to this extent? Again, in continual change of methods, the cost of plant equipment is being constantly reduced. Early-day plants cost more than latter-day plants, resulting in cheaper service to be furnished by the latter-day plants. Does it seem fair to "junk" the early-day plant which was built in good faith? Further, the unearned increment principle will be put on a firmer basis. All such are problems that should be solved by the engineer.

The writer disagrees with the author as to whether the "Money Trust" is an absolute necessity. The question of proper control is so complicated that it is doubtful whether all conflicting points could be consoled. A powerful money trust unquestionably destroys private initiative. Many an enterprise starts as a result of individual effort. We should do nothing to prevent such initiative, for the reason that many worthy movements would thereby remain unborn. Individual initiative must continue, and to continue there must be incentive, and to have that incentive there must be the anticipation of personal profit. New or under-developed localities would remain dormant if left to the money trust alone.

The author suggests the possibility of an economic rate of investment as regards the public at large; a commercial clearing house, as it were. This is Utopian, but is an interesting thought. It would be quite possible, however, in individual cases of investment, to determine at what rate, for instance, ore bodies should be exhausted in order to produce the most economical results, in the broadest sense,

time being considered. To obtain the ideal expenditure is a nice problem of the calculus, similar to, but more complicated than, the determination of the economical diameter of a pipe line in a power plant so that the value of power lost by friction bears the proper relation to the value of the horse-power generated. Mr. Markwart.

The writer will conclude by agreeing thoroughly with the author that the commercial or big business is here to stay, but we must temper it with the esthetic, to the end that what we do is good and great, whether it be the development of an idea or a piece of construction. Our acts and our engineering should be good to behold. Even a monument here and there, as in the time of the ancients, will do us no harm.

Morgan Cilley, Assoc. M. Am. Soc. C. E. (by letter).—This paper deals with a phase of the Profession which has received very limited thought; indeed, too little; but, of course, pressure of affairs has prevented the engineer from devoting to it the time which, otherwise, he would have liked to give. Mr. Cilley.

It is not less important than the subjects which receive more attention, and the neglect which it has suffered has been responsible to a large extent for the lack of appreciation for the engineer and his absence from the councils of higher affairs.

The neglect of kindred lines of study in college is the beginning of the engineer's mistake; he too often sees too much importance in the technical side of his course, and in after life too readily accepts the position of a servant too engrossed in technical details to be bothered with, and, as it is sometimes expressed, "to bother with," managerial councils. Ernest McCullough, M. Am. Soc. C. E., in his paper "Engineering Education in Its Relation to Training for Engineering Work,"* handles this side of the subject exceedingly well in the studies he recommends for the third-year course, and it is in the perfunctory attention to the subjects mentioned that lies the lack of appreciation for the engineer's importance in the social structure as brought out in Mr. Parsons' paper. Does he display the interest in that social structure which would inevitably draw him into the fabric of big things, or, possessing that interest, allow it to languish beneath his engrossment in details?

In fact, the engineer can learn a great deal from the salesman and advertiser. Publicity will benefit the engineer. Just as in business, so in engineering, the consumer has to know where to look for his engineering service. Among engineers there is no need of the strict code of ethics that exists among medical men. Where is the public to find the capable and efficient man, if that person keeps himself practically unknown outside a very narrow circle of acquaintances?

Then, when his opportunity comes, he is at a loss how to present his facts, ideas, and convictions in the briefest yet most telling way.

* *Transactions*, Am. Soc. C. E., Vol. LXXV, p. 1090.

Mr. Cilley. To accomplish this he must have in mind the philosophy of engineering, a working knowledge of psychology, and experience in public speaking, backed by convincing assurance. In fact, he must be a salesman. An engineer from one of the larger engineering offices of New York City, one who had charge of a number of improvement works, once boasted to the writer of having, that day, gone before a meeting of a town council, in connection with his work, and made a telling speech in which he persuaded it to make certain additions to the plans. An average traveling salesman would have thought no more of that than that engineer would have thought of accomplishing a survey which was a little out of the ordinary.

Continuing Mr. Parsons' paper, we read:

"This rigid requirement, that an undertaking must be commercially feasible, strangles the industrial application of many scientific possibilities."

This is only too true, and yet the development of scientific possibilities, which may have seemed at first to be lacking in commercial feasibility, has made the Edison Laboratories the greatest center of valuable invention of history, and also has put the German nation, on account of its government laboratories and government-aided private investigations, in the foremost rank of chemical knowledge and development.

Mr. Parsons argues the importance of the development of scientific possibilities which tend toward the ultimate good of humanity, and on this bases his convictions as to the necessity of a "money trust." Then, as the government is the people, and a money trust holding the accumulated savings of a nation is a necessity, it and the people's government should be one and the same.

The passing of Mr. J. P. Morgan is conceded by all to mark the beginning of a different era of financial arrangements. The economic ills mentioned by Mr. Parsons are traceable to human frailties, and, recognizing this, the people are insisting that their accumulated savings shall not be risked in the power of one man or group of men, regardless of irreproachable character or integrity, unless he or they are directly responsible to them for their acts.

The United States Government has departments which have for their work functions in other fields, similar to those mentioned by Mr. Parsons for his central clearing house, and their acts have the power of the people's government behind them. Then why should it not have a department with the functions the author suggests?

Further, as it would require engineering of the highest order, and in which the Profession would be of greatest importance, why should not this Society, in conjunction with the other great engineering organizations in the country, take the initiative in a movement toward that

end? As engineers have become much better recognized, concerted action on their part would certainly receive attention. If recommendations are based on the deepest thought, give evidence of having been thoroughly considered, be devoid of the least traces of personal or professional ambition, and carry with them the conviction that they are for the far-reaching good of humanity, the movement will succeed. Mr. Cilley.

MAURICE G. PARSONS, JUN. AM. SOC. C. E. (by letter).—The writer's paper has fallen into the hands of men more worthy than he, who have treated it from various points of view, with the matureness of thought which comes from decades of practice, and, as masterly theses on kindred subjects have recently appeared elsewhere, little could now be added advantageously by any one. On the subject of the money trust, however, which at present incurs the disfavor of several factions, the writer desires to make some closing remarks. Mr. Parsons.

Past abuses by this elusory organization must be corrected, not from without, but from within. Only the money trust itself, prior to a much more serious stage of the malady with which the nation is afflicted, can temper its injustices. Voluntarily, when it comes under the control of men big enough to be more generous, it will allow adequate compensation to all producers; for its own welfare, private initiative will be encouraged, the man with a good commodity will be given opportunity to find a market, and will receive a fair reward. Under a stronger and more enlightened money trust, inhuman greed will be peacefully diminished; capital, as capital, will consider the substantial needs of the people, its retainers; and stock exchange juggling will cease. Through the merest common sense, it will correct its many abuses.

Moreover, the control, by a small ring, of much ready money is necessary in order that tremendous undertakings may be accomplished, that new territory can be vitalized as the result of world-wide prolonged conscientious search for that which is most promising. The present crisis of international tension, financial stringency, political and social unrest, could be passed quickly and safely if all bankers, in a spirit of mutual interest, would get together with that end in view—if there were a firmer and better money trust.

Nor is precedent lacking for such a financial authority: The Edison Laboratories are not content with the resources of any one locality. If something is wanted, it is searched for, everywhere, at great cost. As a result of world-wide investigation with central clearing-house reports and decisions, the Edison Laboratories produce handsomely for the use and convenience of man. In political government the individual is not a large enough unit; neither is the family nor the state. We have a national head and even international formalities. Similarly, the individual is normally merged financially in the local

Mr. Parsons. community. Next in order, is a sub-control of local affairs, then an accumulating of resources in some particular bank, and so on.*

Must we not have admittedly a supreme authority in matters of finance, a coterie of international bankers, with its hand on the pulse of the world?

In a broader conception, these men would be members of more than a commercial clearing house. Money is simply a medium of exchange and standard of value. It represents stored-up life, and as such is to be regarded with awe. Those who control it control the lives of the people and the welfare of the nation. All differentialities of human interest are not reduceable by man, with his human frailties and only human knowledge, to precise amounts of money. It is necessary, therefore, that these men have, in addition to ability, training, experience, and judgment, a broad human understanding. Furthermore, they must be men who can oppose with an iron hand, if need be, improper tendencies. Study should be given by them to such matters of national interest as the high cost of living, the pernicious influence on morality of rag-time thought, speech, song, dance, and dress, the fact that in so many cases *viri* has given place to *homo*. World patriots of finance, in the interests of capital, could do naught but afford an "even break" and a "square deal" to each and all, for, to secure perpetually a maximum present worth of net incomes, there must be happiness, loyalty, industriousness, integrity—all the superb qualities—on the part of all the people. Industry should be for the use and convenience of man, for, in the last analysis, it is not bank accounts, but lives and souls, which count. The engineer of to-morrow will be, let us hope, a human engineer.

It were an easy matter to enlarge on the powers of the money trust until it absorbs every function of government. We should then have to ask ourselves where we were coming out; what these all-powerful men might do; and how they would be chosen. Under a pure democracy, we should run the danger of having for our rulers a prize collection of demagogues. With a restricted democracy, we might gradually be overpowered by an oligarchy serving its own end. An inherited monarchy would sometime fall to an imbecile.

As it is to-day, we have a system that works, and no great need exists for a radical departure, although some precautionary measures should be taken. The Reclamation Service and the Department of Commerce and Labor, the one spending many millions of dollars, guided presumably by the ideal theory of investing our money where, when, and in what amounts, it will do the most good, the other serving the people in a sociological sense—these two divisions of government might unite forces, developing into a department-controlling

* The reader is referred to an article on the failure of the First-Second National Bank, of Pittsburgh, in the *Literary Digest*, July 19th, 1913.

industry, but it is hardly likely that such is a necessary step. We have now a government to look after our many needs and troubles. We have financial rulers (the real rulers) deciding our commercial issues. We have individual strong men. On occasion, they are at variance, and unavoidably so, for it is rare for even only two minds to be in perfect accord. Mr. Parsons.

What will be the new philosophy of engineering? Will there be an industry for profit, an industry for abuse, an industry for profit and use, or will there be chaos? We are facing a big problem; one for the individual, educator, and engineer to solve. Social, political, educational, moral, and economic conditions are changing. The concentration of population presents its own difficulties. With all our necessities and luxuries we clamor for more, in the belief that some day we shall have enough to make us happy and industrious. The vast resource of opportunity of the past century has passed with it. Competition from now on must be for quality. Peace prevents the elimination of the strong, sanitation and amelioration of conditions preserve the weak, so that the strong become stronger, the weak, weaker, and competition increases under an artificial selection. This means more bitter disappointment to more losers. The struggle for existence is a relic of the past, but in this game of life, what strife may come? The question is not one of organization, but of philosophy; not of how much property is accumulated, but of the use to which it is put; not of system, but of men. We need a closer harmony between existing working parts.

The big task before the engineer to-day is to help the world out of the uncertainties of complexities, theories, and tendencies—the work of his hand—into a new condition of stable equilibrium. This means sober, industrious, healthy, educated, courageous individuals, in short, good citizens. It means, also, broad-minded, far-sighted, unoppressive industry, good business. A strong and wise government is necessary. Perfect team work between business, government, and people is called for. Fundamentally, the need is always men.

"God give us men! A time like this demands
Strong minds, great hearts, true faith, and ready hands;
Men whom the lust of office does not kill;
Men whom the spoils of office cannot buy;
Men who possess opinions and a will;
Men who have honor, men who will not lie;
Men who can stand before a demagogue,
And damn his treacherous flatteries without winking!
Tall men, sun-crowned, who live above the fog
In public duty and in private thinking:
For while the rabble, with their thumb-worn creeds,
Their large professions and their little deeds,
Mingle in selfish strife,—lo! Freedom weeps,
Wrong rules the land, and waiting Justice sleeps." *

Paper No. 1283

A RATIONAL FORMULA FOR ASPHALT STREET SURFACES.

By J. Alden Griffin, Assoc. M. Am. Soc. C. E.

Every now and then the question is raised: "What is the proper crown to give an asphalt street?" and there is a discussion as to which of the many formulas of to-day gives the best results.

Having been asked this question many times in the past few years, and especially while connected with municipal improvements in Los Angeles, Cal., the writer has given the matter careful investigation, and, by a comparison of the surfaces proposed by the various formulas, has arrived at the conclusion that the crown rise should vary with the cross-fall as well as the grade of the roadway, and that a crown considerably lower than that proposed by the well-known formula of the late Andrew Rosewater, M. Am. Soc. C. E., should be used on streets having a cross-fall between the gutter grades. The writer even favors one which is slightly lower, where there is no cross-fall in the roadway; and, having reached these conclusions, he proceeded to determine the proper amount of reduction to make in the crown for varying cross-falls. After a great many experiments he adopted the following modification of Mr. Rosewater's formula. This gives the best results, using one-eighth of the cross-fall plus ¾ in. as the reduction factor, but some may wish to change $0.12H$ in the formula to $0.10H$, or even $0.08H$, in order not to reduce the crown quite so much; however, the following is recommended:

$$C = \frac{W\,(100 - 4\,p)}{5\,000} - (0.12H + 0.06)$$

in which W = the width of the roadway between curbs, in feet; p = the percentage of grade longitudinally on the street; H = the cross-fall of the street, or the difference of elevation between the high and low gutters, in feet; and C = the height of the crown above the mean gutter grade, in feet.

TABLE 1.

Width of roadway, in feet.	Percentage of grade on street.	Crown, with no cross-fall.	Crown Rise, for Variable Cross-Falls, in Feet.

It will be noticed that on a roadway having a very steep cross-fall the upper gutter will not hold water, which, in the majority of such extreme cases, will do no harm, and will very often save a cross-gutter at the intersection; however, it may be desired at some time to hold the water in the upper gutter, and this may be accomplished, without increasing the side slope of the surface, by shifting the crown to the

upper side of the center of the roadway as shown in Fig. 4, which indicates a special cross-section at that point.

Table 1 is compiled from the formula for the more common roadway widths in Los Angeles.

Figs. 1 to 4 illustrate the comparison between Mr. Rosewater's formula and the modification herein proposed on a 40-ft. roadway

THE STORAGE OF FLOOD-WATERS FOR IRRIGATION: A STUDY OF THE SUPPLY AVAILABLE FROM SOUTHERN CALIFORNIA STREAMS.*

By A. M. Strong, Assoc. M. Am. Soc. C. E.

With Discussion by Charles H. Lee, Assoc. M. Am. Soc. C. E.

Many of the richest sections of California are valleys and plains at the foot of abrupt mountain ranges. The climate is suitable for raising citrus and semi-tropical fruits, but, due to the long summer droughts, this can only be done where there is sufficient water for irrigation. The value of the products has been great, and, beginning with the small irrigation ditches of the Spanish days, the most perfect systems of irrigation in the United States have been built up.

The source of all the water used in these sections is in the streams coming from the neighboring mountain ranges. It is secured by direct diversion, by storage in surface reservoirs, or by pumping from the underground gravel beds fed by these streams. A large part of the total run-off of the streams comes during a short rainy season, or, in the case of those heading in the highest ranges, with the first hot weather of the summer. Rainfall records for 34 years in Los Angeles show that an average of 75% fell during December, January, February, and March, and the run-off of Southern California streams shows a corresponding percentage. In the case of some of the streams head-

* Presented at the meeting of September 3d, 1913.

ing in the snow fields of the Sierra Nevadas, from 12 to 15% of the total run-off comes during a 10-day period in June or July. In the middle and late summer months, when irrigation is needed most, the streams have reached their low-water flow. For this reason many large storage reservoirs have been built, and large areas are irrigated by pumping from underground basins.

As a rule, the area of land which can be placed under cultivation is measured by the quantity of water available, and great expense is warranted in increasing the supply. In many places there are no practical reservoir sites directly on the streams, and in others the available reservoir capacity is only a small part of the total run-off. Even where conditions are most favorable for storage, there are many seasons when it is insufficient for the total flood run-off. Irrigation has now reached a point where all the flow available for direct diversion is in use, and, particularly in Southern California, reservoirs have been constructed on all available sites on the streams. In many places the pumping draft from underground basins is as great as the inflow, or greater. The percentage of the total run-off which can be put to beneficial use can be increased only by diverting the flood flow to reservoirs outside of the natural drainage, or by increasing the flow into the underground basins.

The question of the quantity of water available for storage in this way is becoming very important wherever the water supply for irrigation is extensively developed. The principal problem is the diversion of a large flow from the flood-water for a short time and its storage for a smaller flow during the entire irrigation season. This is now being done in a number of the late projects in various parts of the West. The object of the investigation described in this paper was to get some idea as to the quantity of water now being wasted, but still available for storage in this way. The San Gabriel River, with unusually good records of run-off, was taken as a typical case.

This river drains a large portion of the southern slope of the San Gabriel Range, and is one of the three principal streams of Southern California. The mountain area above the gauging station contains 222 sq. miles, and is somewhat rectangular, as shown on the map, Fig. 1. The elevations range from 1 000 ft. at the gauging station to 10 080 ft. at San Antonio Peak, with an average of about 4 000 ft. To an elevation of about 5 000 ft., the ground is covered with a dense

FIG. 1

growth of brush; above that level there is more or less timber. The geological formation is granite, with a thin soil covering. Precipitation is in the form of rain, except on the higher peaks. Though there are no rainfall records from any station inside the mountain drainage area, practically all the precipitation comes from the general storms shown on the records for the neighboring valley stations, the quantity increasing with the elevation. Below the gauging station, which is at the foot of the mountains, the river flows across the San Gabriel Valley, in a wide gravel wash, through a break in the foot-hills at the Narrows, and across the Coastal Plain to the Pacific Ocean, a distance of about 35 miles.

The gauging station was established by the United States Geological Survey in 1896, and the records obtained since 1898 are said to be very satisfactory. The records of the flow from 1896 to 1902 are published in the form of monthly averages, and are shown in Fig. 2. Since 1902 the daily flow is published in the annual Water Supply Papers giving the surface supply of the United States. The station is well above all tributaries of the river and below the diversion of the power and irrigation canals. A careful record of the flow in the canals is kept, and is given in separate tables, but it is combined with the flow at the gauging station in the diagrams showing the daily flow of the river from 1902 to 1910. (Figs. 3 to 10.)

Years of experience have shown that, for irrigation and power purposes, 80 sec-ft. is the greatest flow that can be counted on for any considerable length of time, and, as a result, this has been the capacity of the diversion canals. Except during the rainy season, this diversion capacity is as great as the total flow of the stream, or greater. Fig. 11 shows the number of days, during each of the eight years, in which the flow exceeded 80 sec-ft., and the duration of the varying flows up to 1 000 sec-ft. The average for those years for which the flow was more than 80 sec-ft. is 148, and that in which it was more than 1 000 sec-ft. is 13½ days. The individual years differ greatly from this average.

No place has ever been found on the drainage area where storage could be obtained, and all the flow in excess of 80 sec-ft. runs down the gravel wash in the San Gabriel Valley. Here a certain quantity passes into the underground storage in the gravel beds, and supplies the numerous pumping plants scattered over the surface of the under-

ground basin. The remainder is now waste water running into the Pacific Ocean.

It is difficult to determine the quantity of water entering the underground storage, as no exact measurements of the waste flow have ever been made. The principal factors governing it are the character of the material in the surface of the wash, the area covered by the stream, the velocity of the flow, the temperature of the water, and the quantity of suspended matter. All these factors will vary with the individual character of the different periods of flood flow. The late W. B. Clapp, M. Am. Soc. C. E., Hydrographer of the U. S. Geological Survey, made some measurements along this line in 1903, but did not consider them at all satisfactory. They showed a maximum absorption of 86 sec-ft., on May 23d, 1903, in the main river channel between the gauging station and the Narrows, where much of the surplus water of the underground storage of the San Gabriel Valley is forced to the surface. As pumping is used extensively in the valley, the greater part of the natural underground flow is now being put to use, and it must be taken into consideration in calculating the available supply for further economic use.

In the case of flood-water diverted from the natural channel for surface storage, it is to be presumed that it will be used for irrigation on territory tributary to the underground basin fed by the stream. All return water would flow into it and go to offset any losses caused by the diversion. The quantity of this return water is not determinable, but it is variously estimated at from 10 to 50% of the water used. Again, any diversion, even up to the maximum economic quantity, will still leave times when there is water flowing in the natural channel, and will simply shorten the time when there is water flowing in that channel. For these reasons it is not considered necessary for any such diversion to pass a large flow in order to maintain the existing conditions of the water supply of the underground basin. Where the diversion is for the purpose of increasing the underground storage, the conditions are somewhat different. The maximum storage possible should be obtained in the natural channel, and a considerable flow should be passed into it before any diversion is made.

During the rainy season of the majority of years there are one or more periods of a few days in which the flow runs into the thousands of second-feet. In these periods the flow is too great and the duration

too short to warrant handling by any diversion. That part of the total run-off of the San Gabriel River which is available for further economic use by storage, either surface or underground, is the flow in excess of 80 sec-ft. plus a reasonable allowance for water entering the underground basin, but not including the extreme floods.

For the purpose of determining this flow, there are available the records of the daily flow for the eight years, as shown on the hydrographs. The only way to test the reliability of any deductions drawn from these records, in relation to long periods of time, is by a comparison with the rainfall records which have been kept for a much longer time. This comparison will only apply to general conditions, for, though the stream run-off is dependent directly on the precipitation, the percentage showing as surface run-off varies greatly. Much depends on the general seasonal conditions and on the character of the individual storms. Fig. 12 illustrates some of the characteristics of the rainfall and run-off during these 8 years. It shows how greatly the percentage of the run-off depends on the conditions under which the rainfall comes. In the season of 1905-06 a few very heavy storms gave a large percentage of run-off, of which a great part was in extreme floods, while nearly the same rainfall in 1908-09, coming in a large number of smaller storms, gave a smaller total run-off with a larger quantity under moderate flood stages. Similarly, the season of 1904-05, with the precipitation falling on a dry water-shed, gave less run-off for all stages of flow. These are only a few of the factors which govern the quantity of run-off resulting from the precipitation of any given season. However, the general seasonal conditions of precipitation give some valuable information in regard to the possible supply for storage.

Fig. 13 is a diagram showing the rainfall for a number of Southern California points. Fig. 14 shows the seasonal rainfall of a number of places near the drainage area, expressed as percentages of excess or deficiency from the long-time mean. These diagrams show that the period from 1897 to 1900 was the dryest in 40 years, or the dryest in 60 years, if the San Diego records are of any value for comparison. This is as far back as the records extend, but early California history indicates that there has been one other period of that kind within the past 100 years. This period might be taken into consideration as a limiting condition, but any short-time average, using the records

during that time, would give results which would be too low. The average rainfall from 1902 to 1910 is very near the long-time average, and the different seasons represent all but very unusual conditions. The season of 1903-04 had a very light rainfall and that of 1906-07 an unusually heavy one. Any conclusions drawn from the records of these eight seasons, except in abnormal cases, should cover the conditions to be met in the future.

AVERAGE RAINFALL FOR 7 FOOT-HILL STATIONS AND
DEPTH OF RUN-OFF FOR DIFFERENT DIVISIONS OF THE FLOW
SAN GABRIEL RIVER

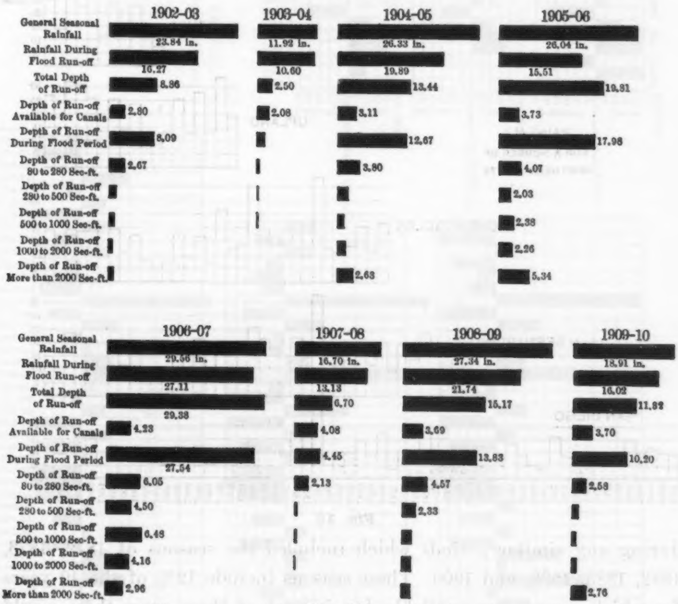

FIG. 12.

In calculating the available supply for surface storage, it is at once evident from the rainfall records that there are a large number of alternating seasons in which the run-off is comparatively small. Any large surface reservoir drawing its supply from a diversion of the flood flow would have to furnish the supply for more than one irrigation with each filling. In order to calculate the available supply for such a reservoir, it is necessary to select a period during which the run-off

represents a limiting minimum condition. Figs. 15 to 18 show the total discharge for the flood periods under consideration and the discharge which would have been available for varying diversion capacities. Fig. 19 shows the discharge curve for all flows up to 1 000 sec-ft. for the several seasons. During these eight years, the period from January, 1903, to October, 1904, gives the limiting minimum condition. The rainfall records indicate that, other things being equal, the supply available during this period, if used during two irrigation seasons, would have been greater than that which would have been available

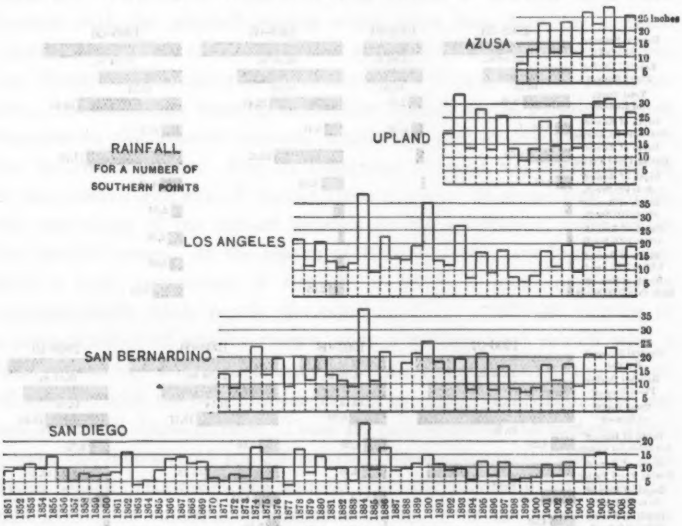

FIG. 13.

during any similar periods which included the seasons of 1872, 1873, 1882, 1883, 1899, and 1900. These seasons include 12% of the 40 years for which records are available, but in each of these years there would have been some storage water, in some of them probably enough for the half-reservoir capacity necessary for one irrigation season.

It was found, during the drought from 1897 to 1900, that practically every irrigation system in Southern California depending on a surface water supply was covering too great a territory for such a period. It was also shown that orchards could be kept alive for one or two years with very little water, the only loss being the crops for those seasons.

FIG. 14.

The increased cost of water for irrigation, if it should be considered necessary to hold enough in storage to cover such a period, would be much greater than the value of the lost crops. Also, the area of land

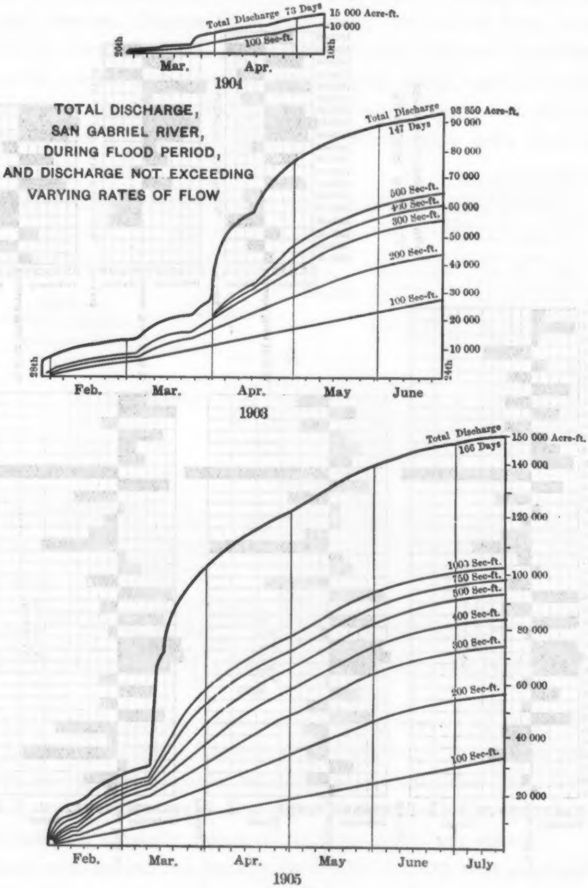

FIG. 15.

which could be placed under cultivation with the existing supply, and the resulting value of that supply, would have to be greatly reduced. Another point that must be taken into consideration is that there can

be a resort to pumping, even if at great cost, to cover short periods of deficient supply. For these reasons it is not thought necessary to consider extreme conditions for the economic minimum supply, and it is thought that the period from January, 1903, to October, 1904, may be taken as the limiting economic condition of the water supply which could be obtained by diversion of the flood-waters of the San Gabriel River for surface storage.

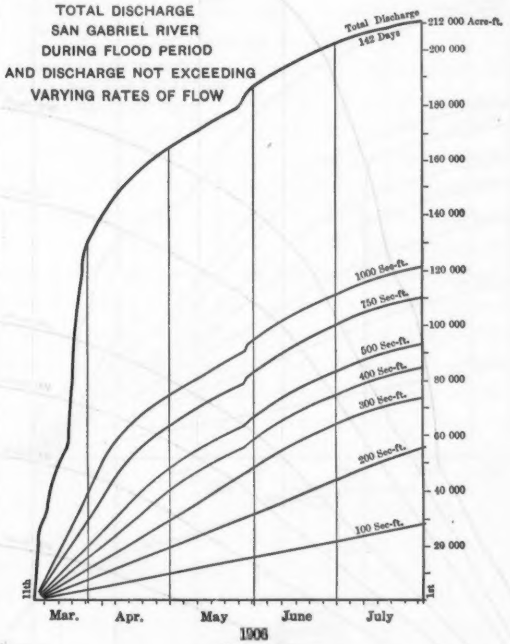

FIG. 16.

The limiting conditions with regard to the available supply for increasing the storage in the underground basins are somewhat different from those for surface storage. The slow movement of the underground waters tends to equalize the varying flows of the different years, and the great extent of the underground basins gives almost unlimited storage capacity. Where the present pumping draft is as great as the natural supply, or greater, the full capacity of these basins, above the limit of economic pumping, is available for in-

creased storage. The ultimate supply available is the total flood run-off of the maximum year; but, as the cost of spreading the water or delivering it to shafts and galleries would be considerable, the economic limit is where the value of the stored water will warrant the expense of obtaining the storage. Although this will vary with each individual case, as a general average, this limiting condition is taken as the maximum supply which can be relied on for an average of one year out of three. In this case, again, short periods of extreme flood cannot be considered as available.

For the eight years under consideration, the season of 1908-09 meets this condition for the San Gabriel River. The rainfall records show that in 30% of the 40 years for which such records are available, the rainfall was greater than for that season, and for 70% it was less. It would seem probable that, if the flow records for the seasons for which the rainfall records were available, this season would still meet this limiting condition.

The measured run-off of the San Gabriel River shows that, for the period from January, 1903, to October, 1904, there were 210 days in which the flow was more than the 80-sec-ft. capacity of the present diversions. During that time a little more than 76 000 acre-ft. passed by these diversions and down the wash in the valley. Of this quantity 46 000 acre-ft. could have been handled by a diversion having a capacity of 500 sec-ft. During these two seasons, there were 57 500 acre-ft. available for the present canals with the 80-sec-ft. capacity. Similarly, during the season of 1908-09, nearly 136 000 acre-ft. passed the diversion point of the present canals in 175 days, with 81 500 acre-ft. available for a 500-sec-ft. diversion. During the entire season, 44 000 acre-ft. were available for the canals. If it were possible to obtain storage for this water at an expense warranted by its value, it would be possible to double the area now irrigated from the surface flow of the river.

The ratio between the capacity of the diversion and the discharge through it during the flood season is much smaller for large diversions than for small ones. In the case of surface storage, the diversion canal would be a large factor in the total cost, and, in increasing the underground storage, the number of basins or shafts and galleries would be one of the main factors. The size of the diversion which would give a discharge warranting the expense of the storage is a matter

DISCHARGE
SAN GABRIEL RIVER
DURING FLOOD PERIOD
FOR VARYING POSSIBLE DIVERSIONS

FIG. 19.

which would have to be worked out in connection with some special project. For the purpose of obtaining an idea of the possibilities of such storage, two assumed cases are given.

The first assumes that a basin in the foot-hills can be converted into a storage reservoir, and that the flood-waters of the San Gabriel River can be brought to it by a diversion canal. The limiting minimum supply is assumed as that for the period from January, 1903, to October, 1904, covering two irrigation seasons. The loss by evaporation and seepage is assumed to be 25%, the duty of water to be 2 acre-ft. per acre, and the value of the water right as $1 000 per inch of annual flow. It is also assumed that, besides the 80-sec-ft. capacity of the existing diversions, a flow of 20 sec-ft. is passed to meet any possible ultimate losses in the supply for underground storage or prior water rights; that is, that no water is diverted until the flow is more than 100 sec-ft., and, when it is more than that, a flow of at least 20 sec-ft. is maintained in the natural channel below the diversions. The details of the results which could be obtained by such a diversion, under these assumptions, are given in Table 1.

TABLE 1.—RESULTS OF POSSIBLE FLOOD DIVERSIONS FROM THE SAN GABRIEL RIVER FOR SURFACE STORAGE.

Diversion, in second-feet.	Discharge, in acre-feet.	Quantity available for irrigation, in acre-feet.	Area irrigated, in acres.	Value of water right.
100	17 700	13 275	3 320	$454 840
200	30 100	22 575	5 644	773 223
300	37 300	27 975	6 994	958 178
400	42 260	31 695	7 924	1 085 588
500	46 180	34 635	8 659	1 186 283
750	48 500	36 375	9 094	1 245 878

In the second case it is assumed that a series of pools, connected with shafts and galleries, each capable of absorbing a flow of 50 sec-ft., is to be constructed to take the flood-waters of the San Gabriel River. The flow taken for the computations is that of the single season of 1908-09. In order to increase the present underground storage, the present water level would have to be raised and the overflow from the low points of the basin increased. It is assumed that this and other losses will take up 50% of the increased supply delivered to the underground basin. Some of the water stored in the season under con-

sideration, and in years when the flow is greater, will have to be used to equalize the deficiency of the dryer years. It is assumed that two-thirds of the water which could be stored during this season would be available for pumping during any one season. The duty of water, as before, is assumed to be 2 acre-ft. per acre. The value of the additional water stored in this way is very difficult to estimate. Under general conditions, the cost of pumping is greater than the cost of maintenance of the distributing system from a surface supply, and the capital invested is less. In this case, as an increase in the underground storage would result in the irrigation of lands now of little value, and would make them of great value, it is assumed that the value of the net available increased storage is the same as that for surface storage, that is, $1 000 per inch for the water right. Besides the present diversion of 80 sec-ft., it is assumed that a flow of at least 100 sec-ft. is to be maintained in the natural channel whenever possible, in order to assure the maximum absorption in that channel. With these assumptions, the details of the different possible diversions are given in Table 2.

TABLE 2.—RESULTS OF POSSIBLE FLOOD DIVERSIONS FROM THE SAN GABRIEL RIVER FOR UNDERGROUND STORAGE.

Diversion, in second-feet.	Discharge, in acre-feet.	Quantity available for pumping, in acre-feet.	Area irrigated, in acres.	Value of water right.
50	12 460	4 153	2 077	$284 549
100	23 420	7 806	3 903	434 711
150	31 920	10 640	5 320	728 840
200	38 240	12 747	6 374	873 238
250	43 360	14 453	7 227	990 099
300	47 600	15 867	7 934	1 086 956
350	51 300	17 100	8 550	1 187 350
400	54 500	18 167	9 084	1 244 508
450	57 220	19 073	9 537	1 306 569
500	59 620	19 873	9 937	1 361 569

The general value of $1 000 per miner's inch for water rights scarcely gives a fair idea of the local conditions in the San Gabriel Valley. At the current rate of 2 cents per inch per hour delivered at the groves, the annual charge per inch is about $175, or 7% of $2 500. This, calculated in acre-feet, gives a warranted investment of $171.23 per acre-ft., including both storage and distributing systems, for the net available stored water, and would warrant the construction of very extensive storage systems.

There are many small streams in Southern California having a run-off which is similar to that of the San Gabriel River, and the only way to get any idea of the available supply for storage from them is by comparison with it. The rainfall on their drainage areas is about the same. It is probable that the run-off per square mile from them is greater than for the average of the total drainage area of the San Gabriel River, and that a larger percentage of it comes in extreme floods. However, it would be possible to handle economically a larger part of the floods from the smaller streams. Under the assumptions given in the two cases worked out, a diversion capacity of 2.25 sec-ft. per sq. mile of drainage area will assure sufficient supply for a reservoir storage of 200 acre-ft. for each square mile, irrigating 40 acres. At 2 cents per inch per hour this would warrant an expenditure of $13 250 per sq. mile of drainage area. In the same way, there would be available for increasing the underground storage a supply sufficient to irrigate 45 acres.

In many places where irrigation is developed extensively, the conditions of run-off are similar to those in the San Gabriel Mountains. Except in a few places, where large natural storage basins have been found on the streams, there is a large waste flood flow. As the value of the land and crops increases, the possibility of obtaining more storage increases. Much remains to be done to secure the maximum possible use of the water supply of almost all irrigated districts.

DISCUSSION

CHARLES H. LEE, ASSOC. M. AM. SOC. C. E. (by letter).—The author has presented in a very detailed and interesting manner the water supply situation on the San Gabriel River, and the writer agrees heartily with his conclusions regarding the possibility of increased use of the flow of Southern California streams by storage. The subject is one that offers an interesting field for engineering endeavor, and the author has laid the foundation for a broad discussion which should be of great value, not only to the Engineering Profession, but also to the inhabitants of Southern California. Mr. Lee.

The writer has been familiar with the water resources of Southern California for a number of years, and during the past year has had occasion to make detailed studies of three important streams, in connection with proposed increased use of the surplus flood. He has been impressed with one phase of storage in this region, which, although mentioned by Mr. Strong, was not particularly emphasized. This is the necessity for over-year storage in addition to monthly regulation, in order to accomplish the greatest beneficial use of stream flow. Mr. Strong has approached the subject with the primary idea of making increased use of the stream flow by regulation of monthly inequalities. The writer believes that permanent increased use of the surplus flow of Southern California streams requires the regulation of annual run-off as well as monthly flow.

TABLE 3.—TOTAL ANNUAL DISCHARGE OF SAN GABRIEL RIVER.

(Compiled from U. S. Geological Survey Records.)

Season, September 1st to August 31st.	Mean, in second-feet.	Acre-feet.	Percentage of mean.

1910-11	376.0	271 600	237
Mean.........	158.9	114 500	100

The necessity for over-year storage is well shown by Table 3, which gives the total discharge of San Gabriel River for the 12-month season,

Mr. Lee. September 1st to August 31st, from the seasons 1895-96 to 1910-11. inclusive, as observed by the United States Geological Survey. It will be noted that during these 16 years the annual run-off has varied from a minimum of 9% of the mean to a maximum of 305%, or from one-tenth to three times the mean. Considering groups of three consecutive years, the extremes have been from 14 to 216%, or from one-seventh to more than twice the mean. The run-off during the 7-year period, 1897-98 to 1903-04, was only 37% of the mean, though that of the following 7 years averaged 176 per cent. Although the 3-year period of drought, 1897-98 to 1899-1900, is of infrequent occurrence, and might be tided over by temporary expedients, yet the benefit to be derived from annual storage is great, and the permanent increased use of stream flow cannot exist without it.

The determination of dependable supply with over-year storage regulation is easily made by constructing a mass-curve of daily discharge in acre-feet for the period of record. The ordinate to this curve at any date represents the aggregate run-off from the initial date of record to the date being considered, and the slope of the curve represents the rate of flow. The mass-curve can be constructed either for the full flow of the stream or for that portion which a transmission system of given capacity will divert. From such a diagram the safe yield of a given reservoir with the known water supply can be determined with precision, or, if desired, the storage capacity necessary for a given draft on the known supply. The writer has found such a curve to be the simplest and most comprehensive form in which to assemble the run-off data of a stream for solving the problems discussed by Mr. Strong, and suggests it as a more satisfactory method of ascertaining the supply available for storage than that used by the author.

The general absence of good reservoir sites of adequate capacity in the mountains eliminates the possibility of surface storage on most Southern California streams. Furthermore, surface storage is not desirable on account of the great evaporation loss. A reliable 4-year record of evaporation from a pan floating on the surface of Sweetwater Reservoir near San Diego indicates an annual depth of 58.7 in., amounting to about 40% of the annual storage. The conditions throughout the valley portions of Southern California, away from the Coast, are similar to those at Sweetwater Reservoir. The losses resulting from extended over-year storage in surface reservoirs in the valleys of Southern California, therefore, would tend to offset the benefit.

Underground storage possibilities in the gravel-filled basins which underlie these valleys have all the conditions necessary for efficient annual regulation. The storage capacity is almost unlimited, the evaporation losses outside the region of outlet are small, and the movement of water through the gravels to the region of outlet is so slow

Mr. Lee.

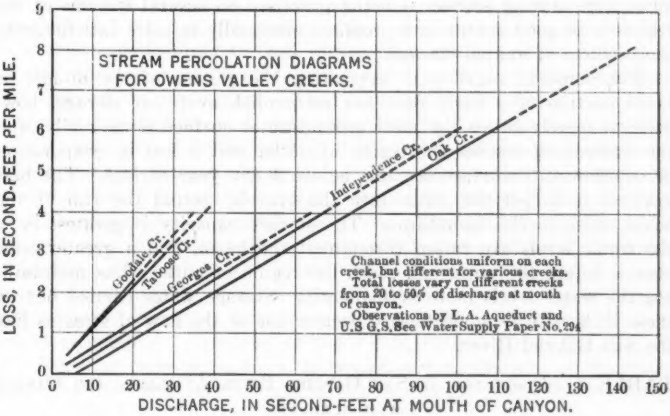

Fig. 20.

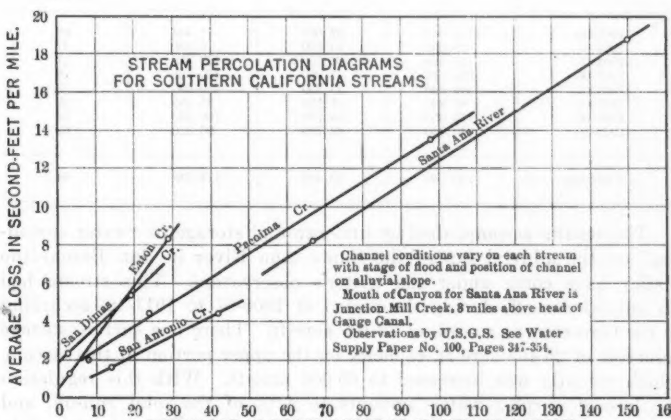

Fig. 21.

Mr. Lee.

that annual as well as monthly irregularities of supply are smoothed out. This type of storage is being practised on several streams of the region with good results and promises eventually to solve satisfactorily the problem of annual storage.

The common practice of saturating the gravels of the middle or lower portion of a basin does not accomplish over-year storage, however; it merely raises the local ground-water surface temporarily, and the water soon reaches the region of outlet and is lost by evaporation or overflow into surface streams before a dry year arrives. The best practice is to get the water into the gravels around the rim of the basin, close to the mountains. The storage capacity is greatest here, the water levels are raised throughout the basin, and a greater time elapses before the water can reach the region of outlet, thus maintaining the water levels more permanently. Storage water carried out on these lines will do much toward greater use of the flow of streams like the San Gabriel River.

TABLE 4.—Discharge of San Gabriel River Available for Canals and Surplus.

(Prepared from Author's Data.)

Season.	Total discharge, in acre-feet.	Discharge available for canals, in acre-feet.	Surplus.	
			Acre-feet.	Percentage of total.
1902–03	104 944	33 000	71 944	68
1903–04	29 650	24 500	5 150	17

1906–07	349 540	49 950	299 590	86
1907-08	83 200	47 550	35 650	43
1908–09	179 850	43 720	136 130	76
1909-10	140 040	43 730	96 310	69
Average......	160 140	40 400	119 740	64

The results accomplished by underground storage or "water spreading" on the alluvial fan of the Santa Ana River in San Bernardino Valley have come under the writer's observation. This stream had an annual run-off, during the period of 1900-01 to 1911-12, according to the Government record, of 72 100 acre-ft. There is a surface storage reservoir of 26 463 acre-ft. capacity on the upper portion of this stream, which recently was increased to 65 000 acre-ft. With this regulation the loss of surplus water amounts to 42% of the total run-off, and for the San Gabriel it is 64%, as indicated by Mr. Strong's data (Table 4). The conservation of this surplus by water spreading has been attempted for a number of years on a small scale, but during the last four seasons it has been placed on a permanent basis. From 10 000

to 15 000 acre-ft. annually are now being diverted and stored in the gravels of the San Bernardino Valley, of which about three-fourths are derived from Santa Ana River, thus reducing the lost surplus flow of that stream from 42 to 30% of the total run-off. The annual cost of this work is about 30 cents per acre-ft. stored, including operation and interest on investment. The quantity of water stored could be increased considerably with very little additional expense per acre-foot. Mr. Lee.

In connection with the subject of natural underground storage, the writer has had occasion to make careful and extended measurements of percolation from gravel stream channels in Owens Valley, and has found that, for stable channel conditions, a straight-line relation holds between loss in second-feet per mile of channel and total discharge (Fig. 20). Although, as the author states, the measurements of absorption on the San Gabriel River by the United States Geological Survey are not satisfactory, yet on other Southern California streams the data are more complete. Analysis of these data indicates that the straight line holds for percolation from the gravel stream channels of Southern California, for moderate discharges, where channel conditions are fairly stable (Fig. 21). The conditions on the Santa Ana River correspond closely to those on the San Gabriel, and give an idea of the extent to which absorption occurs through natural processes.

Paper No. 1285

THE PREWITT RESERVOIR PROPOSITION.*

By J. C. Ulrich, M. Am. Soc. C. E.

The Prewitt Reservoir Proposition was conceived and developed by the Great Western Sugar Company for the purpose of increasing the effective water supply of the lower South Platte Valley, in the vicinity of Sterling. This Company, strictly speaking, is not engaged in the business of promoting irrigation propositions, but in the manufacture of sugar from beets. Though the promotion of irrigation propositions is not, in itself, one of its functions, it has a very definite indirect interest in the effectiveness of the water supply of the regions in which it operates.

Farmers will not raise beets, except at a profit, and beet culture cannot be conducted at a profit to the producer, except in regions in which a certain supply of water is available for use well into September.

This Company owns and operates three important sugar factories in the valley of the South Platte River: At Sterling, at Brush, and at Fort Morgan. The combined daily capacity of these plants, during the sugar-making campaign, is nearly 3 000 tons. In order that their operation may be profitable, it is necessary that they be supplied with a sufficient tonnage of beets to keep them running at least 100 days during each season. This requires about 300 000 tons of beets.

* A paper read before the Colorado Association of Members of the American Society of Civil Engineers, on January 11th, 1913, and presented before the American Society of Civil Engineers at the meeting of September 17th, 1913.

SHOWING CONCRETE PROTECTION ON WATER FACE AND INTERCEPTING TRENCH

FIG. 2.

After these sugar plants were constructed, it was found that, in some years, the water supply was not sufficient, during the later part of the growing season, to effect a full yield of beets; the result was that the supply of the latter was reduced, and the operating time of these factories was curtailed to a period which was too short to give a profit from their operation. In one season it was even found necessary, on this account, to close one of the factories entirely.

The enforced idleness, throughout an entire season, of a plant representing an investment of nearly $1 000 000 is not a proposition to be viewed with equanimity, and, in order to lessen the probability of its recurrence, the Sugar Company conceived the idea of adding to the effective water supply by the creation of an additional plant for the storage and conservation of the water supply existing but not yet made available for the requirements of this region.

The Prewitt Reservoir Proposition contemplates the storage, and conservation for use in the latter part of the growing season, of about 32 000 acre-ft. of water, in addition to that which has been heretofore available.

This proposition has been conceived, financed, and developed by the Great Western Sugar Company, and has been delivered to the Iliff and the Logan Irrigation Districts, practically at the actual cost of construction of the works; the Company, in reimbursement for its expenditure, accepting the bonds of the two districts at par.

The Iliff Irrigation District.

The Iliff Irrigation District comprises an area of about 13 600 acres of cultivated land, extending along the South Platte Valley from a point about 7 miles down the river from Sterling, to a point about 32 miles below that town.

Most of this area is well improved and under cultivation. It is irrigated at present, and has been for many years, by direct diversion from the river, through the following ditches: The Iliff and Platte Valley, the Powell and Dillon, the Harmony (Ditches Nos. 1, 2, and 3), the J. B., the Bravo, and the Powell and Bland.

The Logan Irrigation District.

The Logan Irrigation District comprises, also, an area of about 13 600 acres, extending along the South Platte River from a point

about 14 miles up the river from Sterling, to a point about 6 miles down stream from that town.

Like the Iliff District, this area is well improved, and has been under cultivation for many years. Its water supply is dependent on direct diversion from the river, through the following ditches: The Pawnee, the Springdale, the South Platte Extension, and the Davis Brothers.

The territory in both these districts is well improved, and has enjoyed a reasonable degree of prosperity, without the advantage of an impounded water supply. It is hoped that this prosperity will be increased materially by the more certain water supply which is expected under the operation of the proposition here under consideration.

The Prewitt Reservoir Proposition.

The Prewitt Reservoir Basin consists essentially of a shallow sandy depression on the plains bordering the South Platte River. It is about 2½ miles from the South Platte River, about the same distance from the Town of Merino, on the Julesburg Division of the Union Pacific Railroad, and 13 miles southwest from Sterling.

Its improvement has consisted of the construction of an earthen embankment, about 3½ miles long, occupying about one-third of its contour; the construction of an inlet canal, 5 miles long, from the river, and an outlet canal, 2 miles long, designed for returning the impounded waters to the river for re-diversion through the ditches previously named, and application to the lands of the districts.

The Reservoir Embankment.—The reservoir embankment has a maximum height of 36 ft. This height is reached at only one place, and extends for a distance of less than 100 ft. For the greater portion of its length, the height does not exceed 25 ft., the average being about 20 ft.

It is designed with uniform slopes of 2 horizontal to 1 vertical, on the water side. Where the height does not exceed 20 ft., the outside slopes are also uniformly 2 horizontal to 1 vertical. Where the height exceeds 20 ft., the outside slopes, from the top of the embankment to an elevation 20 ft. below the top, are, likewise, 2 horizontal to 1 vertical, and, from this elevation to the base of the fill, they are 3 horizontal to 1 vertical. The top width, throughout, is 16 ft., and the crest is 7 ft. above the level of the highest proposed water in the reservoir.

FIG. 3.—PLACING CONCRETE PROTECTION SLABS ON FACE OF RESERVOIR EMBANKMENT.

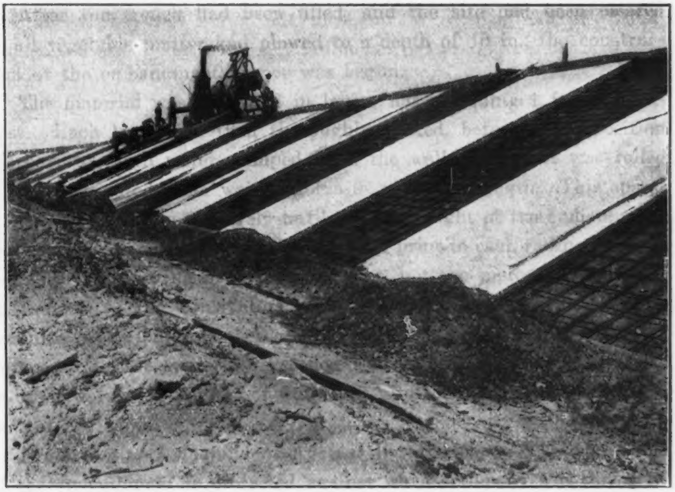

FIG. 4.—COMPLETED SLABS, AND REINFORCEMENT READY FOR CONCRETE FOR ALTERNATE SLABS.

The material on which the embankment is founded, and of which it is constructed, consists essentially of very fine sand mixed with a small percentage of soil.

Prior to the construction of the embankment, a longitudinal trench was excavated along the entire site, its center line being coincident with that of the embankment. This trench was made 6 ft. deep and 6 ft. wide on the bottom, with side slopes of $1\frac{1}{2}$ horizontal to 1 vertical.

Before depositing any earth for the embankment proper, this trench was partly filled with water, in which selected material was deposited in 2-ft. layers. This operation was repeated three times in the filling of the trench. The water for this purpose was pumped from a series of sixteen wells, put down just outside of the lower toe of the embankment, at intervals of about 1 000 ft. Sufficient water was thus furnished and used, to effect, not merely the moistening, but the actual puddling, of the material deposited in the trench.

The purpose of this puddled trench was to break the continuity of any seam which there might be between the soil of the site and the material of the superimposed embankment. It was also designed to cut off and intercept the channels of any dog or gopher holes which might be in the material underlying the embankment.

After the trench had been filled, and the site had been cleared of all vegetable matter and plowed to a depth of 10 in., the construction of the embankment proper was begun.

The material was deposited in layers not exceeding 1 ft. in thickness. Each layer was then thoroughly wetted, before the deposition of the next, with water pumped from the wells. Then it was rolled with a corrugated roller weighing 125 lb. per in. of length. This operation was repeated successively until the full height of the embankment was reached. The wetting of this material prior to each rolling resulted in the actual wetting of the whole layer, not the mere moistening of the surface. The contractors claim to have kept records of their pumping operations, and these disclose the fact that the volume of water pumped into the material exceeded that of the embankment itself; in other words, the volume of water put into the embankment exceeded that of the earth.

Protection of Embankment Against Wave Action.—The water side of the embankment is protected against wave action by a covering of

concrete, 4 in. thick, extending from its foot to within 2 ft. of its top, where it joins a vertical parapet wall of concrete. The latter is 3 ft. high, and extends 1 ft. above the crest of the embankment, and 8 ft. above the elevation of the highest proposed water in the reservoir. This parapet is 6 in. thick, and is L-shaped, with a vertical leg of 3 ft. and a horizontal leg of $2\frac{1}{2}$ ft. Both legs are reinforced in each direction with $\frac{3}{8}$-in. square, twisted bars at intervals of 12 in.

At the foot of the surface protection, and connected therewith by reinforcing rods of steel, there is a vertical "toe-wall," extending 5 ft. into the ground below the edge of the latter. This toe-wall is 6 in. thick, and is reinforced horizontally and vertically with steel bars at intervals of 12 in.

The concrete sheathing which covers the surface of the embankment is in individual slabs, each 10 ft. wide, and continuous in length from the parapet wall at the top to the toe wall at its foot.

These slabs were laid in two distinct sets, the first set being placed with intervening spaces of the same widths as the slabs themselves. After the first ones had become thoroughly set, the alternate slabs were placed. Side forms were placed for the first set of slabs, but their edges constituted the forms for the alternate set.

Under each line forming the junction of adjacent slabs, and designed for the purpose of breaking the joints between the latter, there are concrete stringers, extending from the top to the bottom of the inclined surface to be protected. These stringers are 6 in. thick and 12 in. wide, and each is reinforced with three bars of $\frac{3}{8}$-in. square, twisted steel, placed midway between the upper and lower surfaces of the stringer. The edges of adjacent protection slabs are coincident with the center line of these stringers, each slab lapping over the stringer 6 in. It was expected that this arrangement would break the joints between the edges of the slabs, and prevent the removal of sand and earth through seams which might be caused by the contraction of the slabs.

The slabs are reinforced in both directions with $\frac{3}{8}$-in. square, twisted, steel rods at intervals of 12 in. Great care was taken to ensure that these rods would be midway between the two surfaces of the concrete. The longitudinal and cross-rods were secured to one another with wire fastenings at each alternate intersection.

The concrete in all this revetment was composed of 1 part of Ideal

FIG. 5.—TOE-WALL IN THE FORMS.

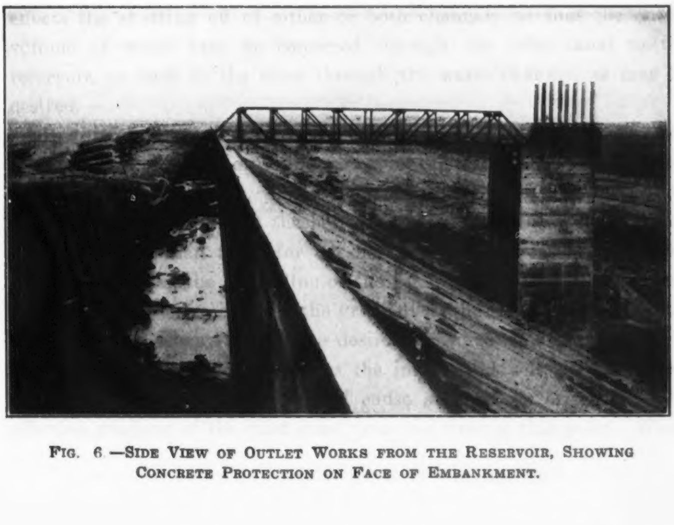

FIG. 6.—SIDE VIEW OF OUTLET WORKS FROM THE RESERVOIR, SHOWING CONCRETE PROTECTION ON FACE OF EMBANKMENT.

Portland cement and 4 parts of clean, sharp, river sand. Gravel was not used because none was obtainable within permissible transportation limits.

The Inlet Canal.—The inlet canal, conveying the water from the river to the reservoir, is 5 miles long, and is on a gradient of 0.025 per 100, equivalent to about 16 in. per mile, the computed velocity being 2.9 ft. per sec., with the canal running full.

The canal has a uniform bottom width of 20 ft., and side slopes of 2 horizontal to 1 vertical. It is built through a comparatively level country, and has an embankment on each side. The top width of these embankments is 10 ft., and the crest elevation is 9 ft. above the bottom of the canal and 2 ft. above the elevation of highest water.

The canal is located mostly on tangents, there being only six curves, of which the sharpest is 6 degrees. Its computed discharge, for a depth of 7 ft., is about 695 cu. ft. per sec.

About 1 mile below the point where the canal is diverted from the river, a waste channel extends back to the river, a distance of 1 mile. This has been designed to assist in removing sand from the canal. It has a bottom width of 24 ft., side slopes of 2 to 1, and is designed to carry water to a maximum depth of 5 ft. It has an embankment on each side with top widths of 10 ft. and crest elevations 7 ft. above the bottom of the channel.

At the origin of this waste canal there is a double structure which effects the shutting off of either or both channels, so that the entire volume of water may be conveyed through the inlet canal to the reservoir, or back to the river through the waste channel, as may be desired.

In this structure there are two sets of regulating gates, one across each channel. There are nine gates in each set, each gate serving to close an aperture 4 ft. wide. The tops of the gates in each set are at the same elevation, but the bottoms of those for the waste channel are 2 ft. lower than those for the inlet canal. The latter are at the same elevation as the grade line of the inlet canal. This arrangement was made in order to increase the gradient in the first mile of the inlet canal at times when it might be desired to sluice sand out of it. At such times, the check-gates across the inlet canal will be closed, and the waste-gates opened, which will cause an increase of 2 ft. in the effective gradient of the inlet canal from the river to this point. When

the sluicing operations are concluded, the waste-gates will be closed and the check-gates opened, thus restoring the normal gradient in the inlet canal.

Structures on the Inlet Canal.—The head-gate at the origin of the inlet canal is of concrete, reinforced with ½-in. square, twisted, steel bars, and is founded on round piles, driven 12 ft. into the ground. It has nine 4 by 9-ft. apertures, closed by steel gates operated by rising screw stems, 2½ in. in diameter at the root of the thread. The gates are raised and lowered by hand-wheels, operating on steel balls running in bronze grooves.

The sides, partitions, and floors are 12 in. thick, and are reinforced with ½-in. square, twisted, steel bars, in horizontal and vertical pairs, at intervals of 12 in., making 4 lin. ft. of reinforcing rod to each cubic foot of concrete.

The double structure at the point where the waste canal originates is composed of two parts, each in all essential respects similar to the head-gate just described, except that the heights of the gates differ, and the waste structure has a drop of 3 ft. beginning a short distance behind the gates, thus combining the functions of a waste-gate and a drop.

There are four concrete drops on the inlet canal, designed for the purpose of accommodating it to the fall of the country in excess of that required for the gradient of the canal. Three of these lower the grade of the canal by 3 ft. each; the fourth is at the terminus of the inlet canal, where it enters the reservoir basin, and consists of two successive drops of 5 ft.

In all cases these drops consist of reverse circular curves in vertical planes, and the sides of the structures conform to the section of the canal, with slopes of 2 horizontal to 1 vertical. Each has five cut-off walls extending below the floor and sides to depths of 5 ft. or more. These walls rest on round piles, driven 12 ft. into the ground. The sides, floors, and cut-off walls are in all cases 12 in. thick, and are reinforced in the manner described for the head-gate structure, involving 4 lin. ft. of steel rod for each cubic foot of concrete.

There are nine bridges crossing the canals of this system. These are all steel spans on concrete abutments, no obstructions being permitted in the channels, aside from the partitions in the head-gate and bifurcation structures, which could not be avoided.

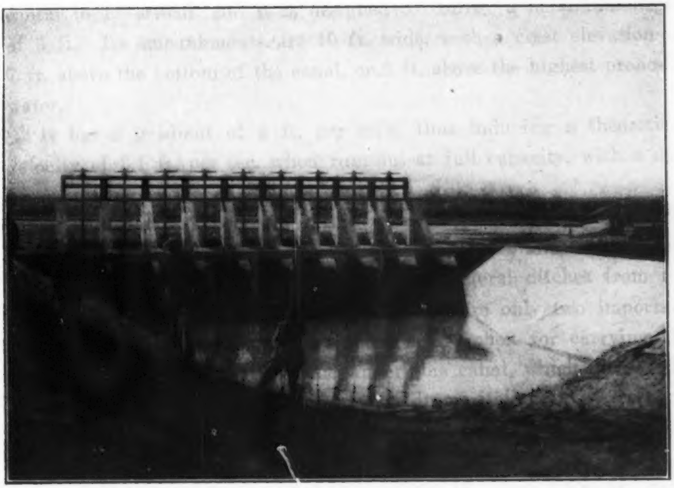

FIG. 7.—REAR VIEW OF HEAD-GATE STRUCTURE, HEAD OF INLET CANAL.

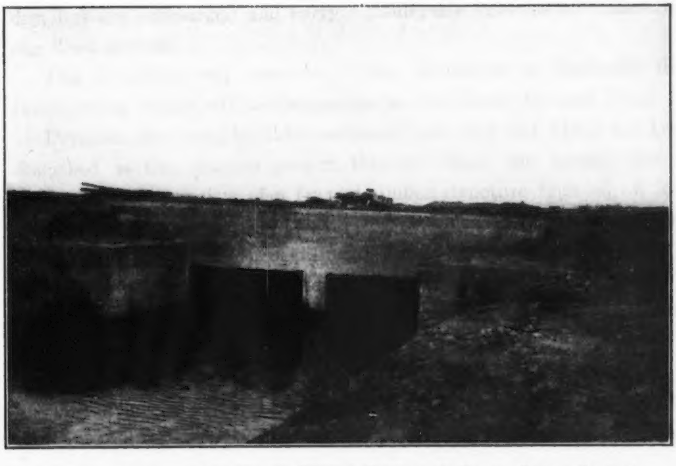

FIG. 8.—CONCRETE CULVERT OR SIPHON CONVEYING CANAL UNDER OUTLET CANAL FROM RESERVOIR.

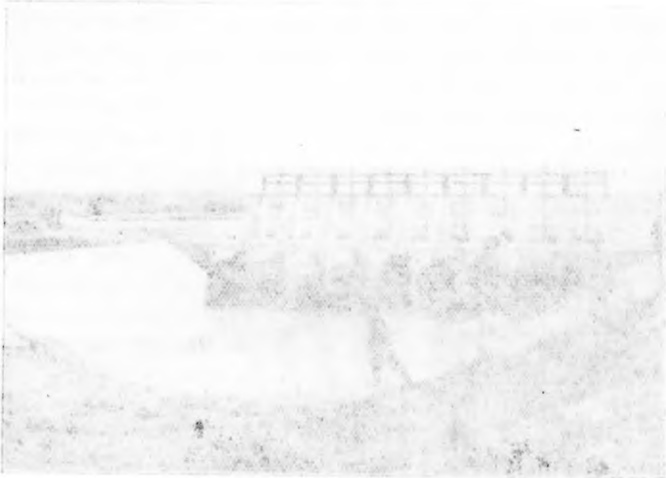

The Outlet Canal.—The outlet canal from the reservoir to the river is 2 miles long. Its bottom width is 22 ft., its side slopes are 2 horizontal to 1 vertical, and it is designed to convey a maximum depth of 5 ft. Its embankments are 10 ft. wide, with a crest elevation of 7 ft. above the bottom of the canal, or 2 ft. above the highest proposed water.

It has a gradient of 2 ft. per mile, thus inducing a theoretical velocity of 3.1 ft. per sec. when running at full capacity, with a discharge of about 525 cu. ft. per sec.

In addition to a concrete rating weir, a distribution gate for delivering water to the South Platte Extension Ditch, and two concrete siphons for conveying the water of certain lateral ditches from the South Platte Ditch under its channel, there are only two important structures on this line. One of these is a siphon for carrying the waters of the South Platte Ditch under this canal, which crosses the line of the latter; the other is a 5-ft. drop, similar in all respects to those already described.

The River Diversion Weir.—The river channel, at the point of diversion of the inlet canal, has a width of about 1 500 ft., from bank to bank. Only about 400 ft. of this distance, however, carries water during ordinary stages of the river. The remainder consists of low-lying lands traversed by minor channels, which are ordinarily dry, but are submerged and carry considerable volumes of water during flood periods.

The diversion weir consists of two structures of distinctly different types, which will be designated as Divisions One and Two.

Division One occupies that portion of the river bed which has been described as the channel proper, through which the normal flow is discharged. It consists of a framed timber structure founded on four rows of round piles driven 12 ft. into the sands of the river bed, and two rows of Wakefield sheet-piling designed as cut-off diaphragms for preventing the passage of water under the structure. Each piece of the Wakefield sheet-piling, consists of three pieces of 2 by 12-in. plank, 12 ft. long, fastened with 60-penny wire spikes, in the form of a tongued and grooved member.

This structure has on its top a movable device which can be elevated or depressed, as may be desired. In periods of very high water, when

the adjoining lands would be in danger of overflow, it is intended that this movable superstructure will be depressed, giving a larger waterway for the passage of flood-waters. At other times, when the flow is normal, it will be elevated, raising the surface to the elevation of highest water in the canal.

The crest of the fixed structure is about 2½ ft. above the natural surface of the river channel and 5 ft. above the floor of the head-gate of the inlet canal, the latter being 2½ ft. below the natural bed of the stream. The movable device permits of the elevation of the effective crest by 2 ft.

This division of the diversion weir is provided with two sluice-ways, regulated with flash-boards, which when opened permit the water in front of the weir to be lowered to an elevation 2 ft. below the crest of the fixed structure. One of these is at the end of the weir next to the head-gate; the other is near the middle of the portion designated as Division One. Each is 30 ft. wide and is divided into six 5-ft. openings, separated by steel girder diaphragms designed for supporting flash-boards. The length of this division of the structure is 435 ft.

Division Two of this structure occupies, and closes permanently, that part of the channel which in ordinary stages of the river is practically without water. It consists essentially of an earthen fill, 20 ft. wide on top, with 2 to 1 side-slopes, and protected on the up-stream side with concrete in the same manner as the reservoir embankment, except that, in this case, there is no vertical parapet wall at the top of the protection.

For the purpose of preventing the passage of water through the sands of the river bed under this embankment, a line of Wakefield sheet-piling 14 ft. long was driven along its center line from one end to the other. This sheeting was driven to depths varying from 10 to 12 ft., and its upper ends project above the surface, to heights varying from 2 to 4 ft., and thus extend into the embankment.

The total length of this structure is 980 ft. Its connection with Division One is effected by a concrete wall which rests on piles and is buttressed on the side in contact with the earthen structure. The elevation of the top of this structure is 7 ft. above the fixed crest of Division One, or 5 ft. above the top of the movable superstructure thereof when the latter is erected.

ULRICH ON
PREWITT RESERVOIR PROPOSITION.

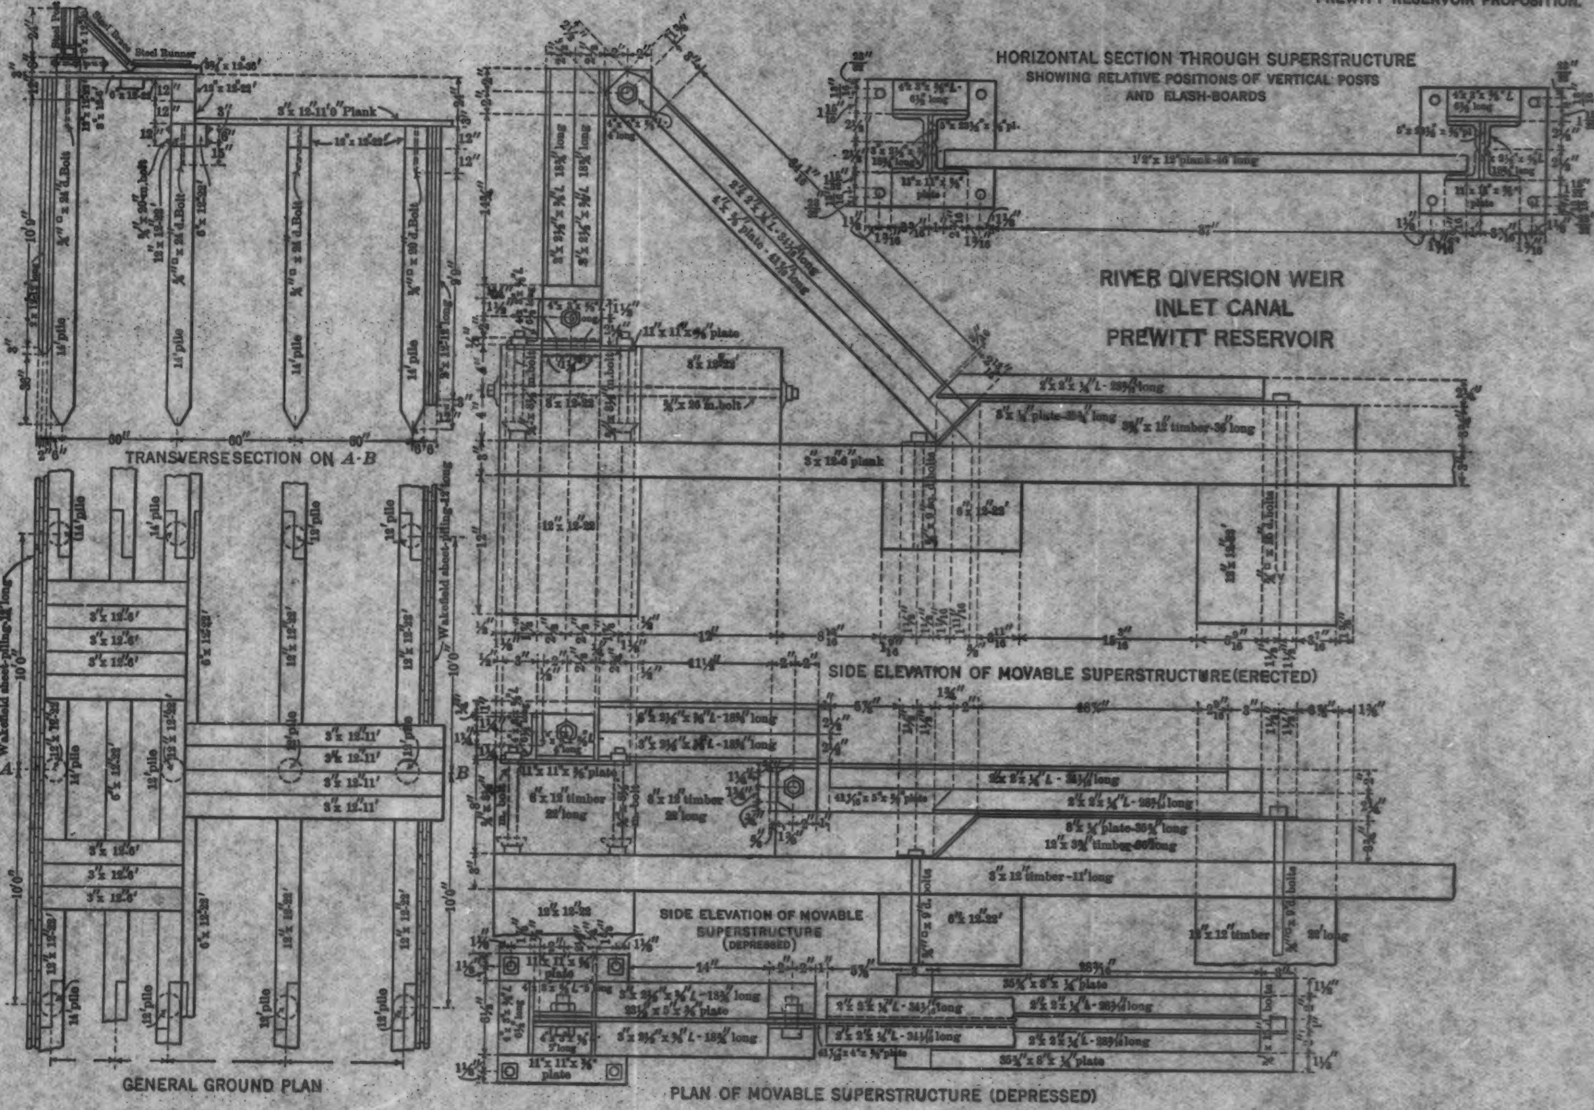

FIG. 9.—THREE-FOOT DROP IN INLET CANAL TO RESERVOIR.

FIG. 10.—DIVERSION WEIR IN RIVER AT HEAD OF INLET CANAL.

General Comments.

It is not claimed for this proposition that it embodies any remarkable or unique features of unusual interest or superiority. The basin itself is by no means typical, its area being out of proportion to its depth. It occupies a site which is very sandy, and it is expected that much water will be lost by percolation and seepage during the early years of its operation.

Its unusual extent of embankment (3½ miles in length), constructed almost entirely of fine sand, and founded on the same material, carries with it a definite liability which cannot be entirely ignored, even though the danger does not appear to be imminent.

In its extremely short inlet of 5 miles, and its outlet to the river of 2 miles, both constructed through a comparatively level country involving no physical problems of difficulty, it has, however, a natural advantage which is not found, to a like degree, in any similar proposition in the South Platte Valley.

The feature of merit which is claimed for this proposition, as distinguishing it from most others heretofore developed by private enterprise in this region, is the substantial and permanent character of its structures.

Aside from the diversion weir across the river at the origin of the inlet canal, there is not a structure in the work which is not executed substantially of reinforced concrete or steel.

All these structures have been built under specifications which were more than ordinarily exacting, and the work has been executed in more definite conformity to the specifications than has been customary in most developments of this character.

With reference to the probable permanence and effectiveness of the works, there appear to be no reasonable grounds for apprehension, aside from the uncertainty that must be faced as to the possibility of protecting effectually an earthen embankment of friable material against the destructive effects of wave action during the high winds which frequently prevail in the plains regions during the spring.

In the writer's opinion, absolute safety, under these circumstances, cannot be predicated of an earthen embankment constructed of material readily responsive to erosion, the protection of which depends merely on a sheathing of concrete covering a material which, in itself, has no power of resistance against the erosive action of moving water.

Though the concrete protection here under consideration has been executed more effectively than can be claimed for most works of this character with which the writer is acquainted, and though its design embodies every precaution that he was able to devise, within the limits of expense that could be borne by the enterprise, he cannot escape the conviction that definite uncertainty exists as to the entire efficiency of this and other works of like character, created with the same end in view.

The development of this proposition involved the placing of 16 700 cu. yd. of concrete, in the composition of which 121 000 sacks of cement, and 660 tons of reinforcing steel were used. In addition to the reinforcing steel, about 90 tons of structural steel were used in building the structures, exclusive of the nine steel bridges crossing the different canals. The total expenditure was somewhat less than $700 000.

Paper No. 1286

ROAD CONSTRUCTION AND MAINTENANCE.

AN INFORMAL DISCUSSION PRESENTED AT THE MEETINGS OF JANUARY 17TH AND 18TH, 1913.

PAGE

(1) CEMENT-CONCRETE PAVEMENTS.

By Messrs. J. A. Johnston, A. H. Blanchard, Sanford E. Thompson, E. H. Thomes, Philip P. Sharples, L. P. Sibley, Samuel Whinery, Harold Parker, William M. Kinney, and James Owen.

Mr. Johnston.

J. A. Johnston, M. Am. Soc. C. E.—Great care is requisite in order to obtain good results in concrete pavements. In discussing the value of such pavements, there is, of course, some question as to the kind and amount of traffic they will stand. In Massachusetts, in 1906, a concrete surface was laid on a section of State highway in the Town of Spencer, and stood the traffic remarkably well. The principal objection was that it was rather hard for the feet of the country-bred horses, which, if allowed to select the traveled way, would turn out on the earth shoulders. A bituminous surface remedied this condition, and at present the road is giving excellent service. The section mentioned was put down by the grouting method, known as the Hassam process. On investigation it was found that the grout had penetrated, not only 6 in. of broken stone, but an additional 2 in. of gravel sub-surface. Very little trouble was experienced from disintegration of the concrete surface; it was confined principally to the area adjacent to the expansion joints.

Since that time some roads have been built by mixing the concrete before placing. Care had to be taken to have the batch properly tempered, particularly in building on a grade. If too wet, the mortar had a tendency to creep and form waves on the surface, and, of course, a dry mixture was not readily flushed, hence it was difficult to get a good smooth surface. The concrete was placed in a single layer, and as near a mosaic surface as possible was desired, in order to permit the bituminous material to bond properly. To obtain that result various methods were tried. After placing the concrete, dry stone was spread over it, and tamped lightly. This worked well, but required considerable skill on the part of the men who were spreading the broken stone. The experiment of allowing the concrete to set for 24 hours, and then brushing it off with a steel broom, gave, perhaps, the most satisfactory results.

There is a tendency to use too lean a mixture for concrete road surfaces. Many engineers have advocated a 1:3:6 mixture, but that is not rich enough, for concrete exposed to the traction of wheels and blows from horses' hoofs must be very tough to resist abrasion. Added strength cannot be gained by reducing the percentage of stone aggregate, that is, assuming 2 parts of sand to be the correct quantity to be used with 1 part of cement. Such a mortar will fill the voids in 4 parts of stone, and no added strength is gained by reducing the stone

aggregate to 3 parts. Too small a proportion of stone means a large percentage of mortar, thus giving a smooth surface, which would be slippery and not desirable. Mr. Johnston.

The concrete pavement has the advantage of being not only a surface, but also a foundation. Though, of course, there may be conditions where some treatment of the sub-surface will be needed, with a uniform soil, in which the frost action is about the same in all parts, there is very little difficulty. If, however, the soil is varied, so that the frost will affect one portion of the road more than another, the concrete will crack. It is an unusual condition where such cracks are serious enough to disintergrate the concrete, and any ordinary cracking is not material. This is particularly true where concrete is coated with a bituminous material, as the cracks are then sealed over and give no trouble. With concrete, as with all other smooth paving, the surface is rather slippery, necessitating care in designing the maximum grades and the camber of the road.

A light bituminous top on a cement-concrete base solves many road problems. It is reported that there is much difficulty in making the bituminous material stick to the concrete. In Massachusetts success has been obtained by the following method: The concrete surface is swept as clean as possible, then sprinkled with water, and while still wet covered with Tarvia A, heated to 200° Fahr. and applied at a pressure of not less than 70 lb. per sq. in., and at the rate of ½ gal. per sq. yd. of surface. This is then covered with clean stone screenings (not exceeding ½ in. in diameter and from which the flour has been removed) spread at the rate of 0.015 tons per sq. yd. of surface. This is again watered, and while still wet a second ¼-gal. coating of tar is applied in the same manner as before, but covered with clean, gravelly sand, using 0.015 cu. yd. per sq. yd. of surface.

The speaker is aware that the application of tar on a wet surface is contrary to existing theories, but it has worked satisfactorily. This road, treated in August, 1910, has cost to date, $15 for total repairs on more than 4 000 lin. ft. of 15-ft. surface, and it has taken only 30 gal. of tar to replace such small places as have scaled off. The speaker believes the successful adhesion of the tar to the concrete is due to the wet surface of the latter and the high pressure used in spraying the tar on the road.

A. H. Blanchard, M. Am. Soc. C. E.—Although cement-concrete pavements have been used in the United States since 1893, various details of construction and maintenance are as yet in an experimental stage. Many miles of cement-concrete pavements have been examined by the speaker, and the only ones which have been observed to be free from cracks are those which have been carefully constructed by the mixing method, and built on a well-drained, thoroughly compacted foundation, with adequate transverse expansion-contraction joints. Such Mr. Blanchard.

Mr. Blanchard.

joints are necessary, if successful results are to be expected, and both longitudinal joints along the curbs and transverse joints should be provided. If there are no expansion-contraction joints, the tensile strength of the concrete will probably be exceeded when the concrete contracts, and the pavement therefore will crack; when it expands, it will tend to bulge, and if the expansion produces forces which are in excess of the compressive strength of the concrete, the latter will crush at the cracks. It is obvious that the edges of the joints should be protected from the abrasive action of traffic, and it is likewise apparent that the joints should be filled with a material which will provide for movement between the joints as the pavement expands and contracts.

The maintenance of cement-concrete pavements is difficult, as it is necessary to keep traffic off the freshly laid patches. It would seem advisable to use a bituminous concrete for patching, and the bituminous cement should be of such a character that the bituminous concrete will be stable after thorough compression by tamping or otherwise. Naturally, a cement-concrete pavement repaired in this manner will not be pleasing from an esthetic standpoint. However, this point is not one of weight, as in all probability a large percentage of cement-concrete pavements constructed in the future will be finished with a bituminous surface.

Mr. Thompson.

SANFORD E. THOMPSON, M. AM. SOC. C. E.—One of the problems to be considered in the construction of concrete pavements is that of expansion and contraction due to changes in temperature. Contraction caused by the lowering of the temperature produces cracks, not only in concrete which is not reinforced, but also in brickwork or stonework. In the latter, however, the cracks are not apt to be so noticeable, because they follow the line of the joints.

Although it is possible to reinforce concrete pavements with steel so that the size of the cracks is inappreciable, the introduction of steel in sufficient quantity for this purpose is somewhat questionable from the standpoint of cost, and the problem, therefore, resolves itself generally into the location of the cracks where they are wanted, so that they will have smooth joints instead of rough, irregular lines.

Longitudinal joints through the middle of the pavement should be avoided if possible. Sometimes, it is advisable to make a longitudinal joint on each side of the pavement next to the curb. The spacing of joints across the pavement depends on climatic conditions and the extremes of temperature that will occur in the given locality. A spacing of from 20 to 30 ft. is common practice in first-class construction. If the concrete is laid in cold weather, at a temperature not very much above freezing, its tendency to contract is less, and the cracks will be apt to occur at a greater distance apart. In some cases, this fact may be taken into account in locating the cross-joints.

Mr. Thompson.

It is possible to calculate quite closely the actual amount of contraction which will take place during a falling temperature, and to determine the approximate size of crack that is likely to open. The coefficient of expansion of concrete is approximately 0.0000055; that is, for every degree of fall in temperature, the concrete contracts in this ratio. Suppose, for example, a section of concrete is 50 ft. long, and that it is free to expand and contract, the actual contraction caused by a fall in temperature of 40° Fahr., theoretically, would be $0.0000055 \times 40 \times 50 = 0.011$ ft., which is about $\frac{1}{8}$ in. In several cases the speaker has had occasion to check this theoretical contraction in actual concrete structures, and has found that it agrees closely enough for practical purposes. In one case, for example, he measured the contraction in a long, reinforced concrete, freight shed in which joints had been left at intervals; another case was in a large reservoir bottom, which was free to expand on one side; a record of the tests in the Croton Dam has been published.*

The necessity for frequent joints, in the first place, is to keep them small in size, and, in the second place, to prevent irregular cracks from opening up between them. There are certain patents on the market for steel-bound joints, which prevent chipping at the edges. It is a question, however, whether it is not more economical to place the joints at fairly close intervals, except where the road traffic is very heavy.

The question of expansion requires very little consideration. Many concrete pavements are built with open joints filled with a bituminous mixture to permit expansion. In ordinary cases, where the pavement is on a uniform grade, this is not necessary, because any expansion will be taken up by the concrete itself, usually by producing compressive stresses.

Many failures of concrete pavements are due to the poor quality of the aggregates. Not only must the sand of the aggregate be clean in appearance, but it also should be subjected to actual test. Sand which passes even close inspection has been found in a great many cases to fail to set properly in mortar or concrete. A very small, almost insignificant, quantity of vegetable matter in the sand—a quantity which cannot be determined by the eye—may prevent the concrete from hardening. An especially good, fine aggregate is particularly necessary in the wearing surface of a pavement, because of the extremely hard usage to which it may be subjected. It is absolutely necessary, therefore, in any pavement used as a wearing surface, to test the sand. A mechanical analysis test is of value to determine the quantity of very fine material, which is especially detrimental to a wearing surface. In addition, however, there should always be a test of the strength of the mortar, made up into briquettes, or cubes, in the proportion of 1 part cement to 3 parts sand, and these specimens should

* *Transactions*, Am. Soc. C. E., Vol. LXI. p. 399.

Mr. Thompson. be compared with similar ones made with the same cement and standard Ottawa sand. For the fine aggregate for a wearing surface, the strength of the mortar containing the sand in question should equal that of the standard sand mortar.

Mr. Thomes. E. H. THOMES, M. AM. SOC. C. E.—The results obtained with the oil-cement, concrete section of the experimental pavements constructed on Hillside Avenue, Jamaica, N. Y., in August, 1911, by the Borough of Queens, in co-operation with the United States Office of Public Roads, may be of interest.

About May, 1912, a number of depressions from 1 to 2 ft. in diameter, and from ½ to 1½ in. deep, had developed in the surface. On account of the traffic, it was impracticable to make repairs with Portland cement, and, therefore, this section was covered with a bituminous seal coat of about ⅜ gal. per sq. yd., applied by Tarrant hand-pouring pots and covered with sand and screenings (0.01 cu. yd. per sq. yd.). The whole section was first thoroughly cleaned by hand-brooming—ordinary, factory brush brooms—and the larger depressions and expansion joints were painted with tar asphalt, composed of Tarvia A mixed with about 15% of oil asphalt. A layer of ¾-in. stone was placed in the deeper, and one of dustless screenings in the smaller, depressions. The whole surface was then covered with a seal coat. Tarvia A was used from Station 0 to Station 0 + 48; tar asphalt from Station 0 + 48 to Station 1 + 52 and from Station 1 + 67 to Station 1 + 73; and Texas asphalt 55 from Station 1 + 52 to Station 1 + 67. The asphalt was applied first in a thin paint coat of 1 part asphalt to 2 parts gasoline, and then covered with the asphalt cement. Sand covering was used from Station 0 + 24 to Station 0 + 80, screenings from Station 0 to Station 0 + 24 and from Station 0 + 80 to Station 1 + 28, and dustless screenings or stone chips from Station 1 + 28 to Station 1 + 73.

In January, 1913, the Tarvia A had scaled off in a few spots, the tar asphalt was about one-third worn off, and the asphalt about one-fifth gone. There is very little apparent difference in the results obtained with the sand, screenings, and stone chips. The sand appears to give the same result as the stone chips, at one-third the expense. At the deeper depressions, the bituminous patches pushed out into waves during the summer.

A 2-in. depression at Station 1 + 73 was cut out and filled with 3-in. creosoted wood blocks with asphalt-filled joints. The wood blocks at this point, along the trolley track, and in the two-course expansion joint at Station 0 + 97, have given good satisfaction, but they are expensive.

A traffic census taken May 18th, 19th, and 20th, 1912, from 7 A. M. to 11 P. M., showed an average daily traffic of 3 330 vehicles, of which 90% was motor traffic.

The speaker has inspected a number of concrete pavements between Boston and Chicago and has not seen any which have been down for

any length of time and are satisfactory for heavy traffic. Some of the Blome pavements in Chicago, Washington, and New Haven, have cracked badly. Most of the concrete pavements in New England have cracked and worn in holes, and have been coated with tar and grit. Mr. Thomes.

A concrete pavement is defined by some engineers as one having a cement-concrete wearing surface, and by others as concrete with a thin bituminous wearing surface. The type referred to under discussion should be clearly stated.

There may be places and conditions where each type is advisable, but it is wise to proceed cautiously with the ordinary class of concrete pavement, especially in the climate of New York. A good, rich, one-layer, concrete pavement, uniformly constructed with a smooth surface and covered with a thin bituminous mat, seems to have some advantages. A good example of this type was constructed in the summer of 1912 by the Hassam Paving Company on the Jericho Turnpike, on Long Island, about one mile east of the New York City limits.

Expansion joints are not advisable in grouted stone block or wood block pavements in which proper longitudinal expansion joints are provided, and it would seem that the same should apply to concrete pavements.

PHILIP P. SHARPLES, ESQ.*—In the application of refined tars on old concrete pavements, the question of adherence is very much harder to solve than in the case of new pavements. On many pavements where there is a great deal of dust, both brought on and due to the actual grinding up of the concrete, it is extremely difficult to obtain a clean surface on which to put the tar. Mr. Sharples.

If the pavement is dampened before the application of the refined tar, it is very important that absolutely all traffic be excluded until there has been a chance for the moisture to dry out from under the surface of the tar. Otherwise the tar does not adhere well, loosens, and will not give good results. In dampening the pavement no free water should be left on the top of the concrete, for in that case, the water tends to float the tar, preventing a good bond. The concrete should be allowed to dry partly, be squeegeed off, or treated in some other way so that no excess of moisture remains.

The tar should be applied in two thin coats. A slight coating of sand or screenings over the first coat is necessary, in order to allow the second coat to be applied. The second coat is filled with sand, screenings or pea stone. In this way a surface about $\frac{3}{8}$ or $\frac{1}{2}$ in. thick is built on top of the concrete. To insure a good wearing surface, it is essential to embed in the tar a hard mineral matter which will resist abrasion.

In repairing old concrete pavements, pot-holes must be considered. It is absolutely impossible to repair pot-holes with cement-concrete in an economical way. It has been found satisfactory, however, to use

* Chief Chemist, Barrett Mfg. Co., Boston, Mass.

Mr. Sharples. tar concrete, but, in doing so, it is important to use stone which will be practically as large as the hole is deep. If fine material is used, the traffic will soon force the tar mixture out of the hole.

Mr. Sibley. L. P. SIBLEY, ESQ.*—It has been suggested that the concrete should be moistened immediately before the application of the bituminous material. It seems to the speaker that there is a great difference between the entire body of the concrete being damp, or dry, and simply sprinkling the concrete immediately before applying the bituminous material. If the entire body of concrete is damp, it seems as if the results must be at least uncertain; but if it is dry, the moisture caused by the light quantity of water sprinkled on the surface would be sufficiently absorbed by the concrete so as not to interfere with the bond between the latter and the bituminous material. The road should be kept closed to traffic for a few hours in order to permit of this absorption.

In the case of bonding between two layers of tar, when the first layer has been covered with screenings of sand, it is very important that these screenings be free from dust or any fine material, no particle of which should be less than $\frac{1}{8}$ in. in size. When the bond is thus constructed, there will be no blanket of dust or fine material over the first layer of tar to prevent the second layer from uniting solidly with it.

Mr. Whinery. SAMUEL WHINERY, M. AM. SOC. C. E.—In the speaker's opinion, every concrete roadway pavement should be laid in two courses—a foundation and a surface course. The same functions are required as in other roadway pavements, that is, strength to support loads, and density and hardness to resist surface abrasion.

The surface course of a concrete pavement should be compounded and laid with something like the same care, skill, and thoroughness as the wearing course of an asphalt pavement. As a rule, this has not been done. Where the second or top course has been used, it has been laid more or less carelessly, with insufficient regard to quality of materials, uniformity of consistency, and thorough work.

Concrete pavements are not suitable for streets of heavy travel. They should never be used where a foundation of 4 in. of ordinary concrete and a surface course of 2 in. of special surface mixture, will not be ample to carry the loads and stand the abrasion of travel. There are, in every city, a large number of streets on which a properly constructed concrete pavement will give entire satisfaction. On such streets it will prove durable, dustless, possess most of the desirable qualities of a first-class roadway pavement, and give a larger return per dollar invested than any other kind of pavement.

The speaker agrees with Mr. Thompson in regard to the necessity of using only the best materials, and of giving special attention to the

* Asst. Eastern Mgr., Barrett Mfg. Co., New York City.

quality of the sand, which should be thoroughly tested. The hardness and toughness of the stone used in the top course is also an important consideration. The speaker specifies that the size of the stone shall range from that which will pass a screen of 1½-in. mesh to that which will be held on a screen of ½-in. mesh. The fine material and dust is objectionable, because of its tendency to segregate in the mass and because its varying quantity is likely to prevent that uniformity of mixture which is highly desirable. He requires that the sand shall be screened, that it shall be of grains of such size that 75% of the whole will fail to pass the No. 30 sieve, and that it shall be tested with regard to the strength of mortar made with it. This is important in view of recent unsatisfactory experiences with apparently good sand. A ratio of 1 part of cement to 2 parts of sand for the mortar is probably rich enough. In some recent specifications the speaker has called for ratios of 1:3:6 for the foundation course and 1:2:3.75 for the surface course, but in the compacted mass the volume of mortar should exceed that of the voids in the stone by from 7 to 10 per cent. The ideal surface-course mixture is one in which the largest practicable ratio of the mass is stone with sufficient strong mortar to hold the fragments firmly in place. The speaker tries to insist that this surface mixture shall possess great uniformity in composition and consistency. This requires: careful measurement of all the materials, including the water; that special care be taken to prevent segregation in the mixer or on the street; and that it shall be properly and uniformly graded and compressed to a true surface on the street; in short, that especial care shall be taken to make a concrete as nearly perfect as possible. Mr. Whinery.

It is very important that the surface course be laid and tamped on the foundation course before either begins to set. This requires that the construction of the two courses be carried on simultaneously.

The surface course should be finished with a roller, not only to perfect the consolidation, but to secure a true surface, which latter is nearly as important as in the case of asphalt pavement.

Finishing the surface with neat mortar or by troweling should be prohibited.

Our knowledge relative to expansion and cracking is as yet meager. Concrete pavements often crack where apparently ample expansion joints have been provided, and frequently where least expected. Where these natural cracks or joints occur, the wear along their edges, as a rule, is less than along those of artificial expansion joints. This is probably due to the fact that the wood or metal forms used for making the joints prevent the same uniformity of composition and density of the concrete along them as in the body of the work. To prevent this, it is better not to use such joint forms, but to cut the expansion joints through the concrete after it is laid. It is an open question at present whether it is not better to omit all expansion joints (except along the

Mr. Whinery.

curb) when the pavement is laid, and to let the concrete select and make its own expansion (or rather contraction) joints. These cracks should then be filled with bituminous cement, after being cleaned out as well as possible with proper tools and by water jets from high-pressure hose.

The question of the advisability of applying a coating of asphaltic oil to the surface of the pavement, is not yet settled, but there is every reason to believe that, if suitable material is used and the work is properly done, it will be decidedly advantageous.

Mr. Parker.

HAROLD PARKER, M. AM. SOC. C. E.—A concrete pavement is most desirable, provided it is properly laid; but, to obtain a uniform mixture and apply it uniformly all over the road is a problem not easy of accomplishment.

To secure a uniform concrete mixture on a road, the stone should be of absolutely uniform thickness, and rolled down so that the road is finished, as to cross-section and quantity of stone, before any cement is added. Whether mixtures are made on a board or in a machine, the very fact that the concrete has to be transported and put on the road in batches, destroys its uniformity, because of the difference in the specific gravity of the materials used. A perfectly uniform road, therefore, is impossible. This can be remedied in a measure by the care that is used in making the mixture and putting it down, but the only reliable concrete road is made, as the speaker has stated, by placing the stone without binder on the road bed and rolling it thoroughly before the cement is applied.

A properly constructed concrete road is the most indestructible surface that can be built except a stone pavement. Wherever the traffic is sufficiently heavy, or of a character to warrant it, a concrete foundation should be built for any surface.

The bituminous surface on a concrete road should be applied in very thin layers, as such a coating can be maintained at small expense. It can be put on under pressure, which gives a perfectly uniform quantity of bituminous material at very trifling expense. A defect which occurs in a road thus treated is so slight in elevation that it will not be felt by the ordinary traffic going over it, whereas a defect in a top surface of 2 in. or more, soon becomes a material one, which every vehicle feels. It also increases very fast, and disintegration once begun continues rapidly.

Mr. Kinney.

WILLIAM M. KINNEY, JUN. AM. SOC. C. E.—From the examination of more than 100 concrete pavements, during and after construction, in various sections of New York, Pennsylvania, Maryland, and other States, the speaker has come to the conclusion that the use of bank-run material or crusher-run limestone is almost sure to result in failure. The aggregates should be screened dry over a No. 4 screen, and remixed in the definite proportions desired. A mixture of 1 part of

cement, 2 parts of sand, and 3 parts of gravel or crushed stone (from ¼ in. to 1 in. in size), will give the best results under general conditions. Though a 1:2:4 mixture might be considered better to fill the usual requirement of the ratio of fine to coarse aggregate, the excess mortar in a 1:2:3 mixture will be a distinct advantage in finishing, and, under most conditions, will be satisfactory. Mr. Kinney.

This, of course, presupposes a one-course pavement, which should be selected in all cases where the aggregate available, in the territory in which the pavement is to be constructed, is suitable for a wearing surface. Good practice would recommend the two-course pavement only in places where local aggregate was suitable for the base concrete, but not for the wearing course. In such cases the cost of the pavement might be reduced considerably by shipping in only enough of the more satisfactory aggregate for the wearing course.

The use of steel trowels on a concrete pavement should be prohibited. The wooden float used after the concrete has been struck off to the proper grade with a straight-edge is amply sufficient, and does not draw the fine material to the surface like the steel trowel. The presence of fine material on the surface is objectionable from the wearing standpoint, and also because of increased slipperiness.

The protection of the concrete from premature drying out is an important feature of work of this type. As soon as the concrete becomes sufficiently firm, a canvas cover should be spread over the finished pavement and kept moist. This cover may be removed the next morning, or earlier, if the concrete is sufficiently hard, and the pavement covered with at least 2 in. of sand or earth, which should be kept sprinkled. The wearing quality of a pavement, well laid and of good materials, is often greatly reduced by failure to appreciate this one point of proper protection of the hardening concrete.

Regarding bituminous coatings for concrete pavements, there is this to be said in general: The coating will wear off sooner or later, and conditions in the United States are such that we cannot hope for the immediate replacement of this coating. It is essential, therefore, that the concrete be laid with the same care and attention as if no surfacing were to be applied. There is no hope for a road consisting of 6 or 7 in. of poor concrete and ½ in. of tar or asphalt sprinkled with sand. The question of the application of bituminous surfacing should be considered carefully, as it is certain that methods of application which work successfully with tars do not work well with asphalts, and *vice versa.*

JAMES OWEN, M. AM. SOC. C. E.—In building the Plank Road from Newark to Jersey City, N. J., on the salt meadows which had been filled up to reduce the vibration, it became necessary to provide a roadway during a certain portion of the winter of 1911-12. Mr. Owen.

Mr. Owen. As a matter of economy an 8-in. concrete pavement was laid, with the idea of allowing the traffic on it during the winter and then using it in the spring for a foundation for a permanent pavement. It was about 8 in. thick and about 20 ft. wide on the fills. After the road was partly finished on top, traffic was allowed on it, with the result that the pavement was ground up and went to pieces in about three weeks.

At that time the failure was attributed to some details of the construction and to the very heavy travel. During the summer of 1912 a granite block pavement was laid on one side, with cement grouted joints, under the usual specifications. The grouting went to pieces, although the travel was not allowed on it for from 10 to 20 days after it had been applied. It was suggested that the vibration of the road was the cause of the failure of both sections. It is evident that, in cases where there is a possibility of vibration, the bond of the cement will be impaired and the efficacy of the work destroyed.

(2) COST RECORDS AND REPORTS.

By Messrs. Nelson P. Lewis, L. L. Tribus, W. W. Crosby, George W. Tillson, William H. Connell, A. H. Blanchard, H. W. Durham, and Frederick Wilcock.

Nelson P. Lewis, M. Am. Soc. C. E.—The subject of cost records and reports may be considered from two aspects, the professional and the scientific. Mr. Lewis.

There can be no doubt of the right of the professional man to profit by discoveries and inventions resulting from his own experiments and researches, provided he does not in a professional capacity advise the use by his clients of appliances or processes on which he holds patents and receives royalties. The idea, however, that he may regard the results of his observations and the lessons to be drawn from his own successes and failures as his stock in trade is repugnant to all who appreciate the dignity of professional work and the necessity of high professional ideals. This is especially the case with one who occupies a public office and whose experiments are conducted with public funds. It is true that while some are able to profit by the mistakes of others, there are, perhaps, more who must make the same mistakes themselves before they can learn to avoid them, and, unfortunately, there are still others who appear incapable of learning much either from the mistakes of others or from their own. That is no reason, however, why they should not be given the opportunity to do so. Believing that the professional obligation of the engineer to make public the results of his own experience for the benefit of others will be conceded, this aspect of the subject will be dismissed without further comment.

Our chief interest, then, so far as this discussion is concerned, is the scientific value of cost records and reports. If they are unscientific and inaccurate, they are worse than useless; they are misleading, not only to those who examine them, but also to those who prepare them. They may be accurate as far as they go, and still be unscientific and all the more dangerous because they bear on their face certain evidences of painstaking accuracy, while, owing to their failure to give the precise circumstances under which the work was carried out, the omission of overhead or other charges, and especially owing to a disposition to ignore certain unsatisfactory features of the completed work due to carelessness or lack of foresight, which the engineer in responsible charge is reluctant to admit, erroneous conclusions are likely to be drawn.

The aim of the speaker in these introductory remarks will be, not to suggest certain forms of cost records and reports, but to outline

Mr. Lewis.

briefly some of the fundamental considerations which should govern their preparation and publication. First, we must draw a sharp distinction between cost records and accounting—two very different things. The main object of accounting is to permit of intelligent bookkeeping, to distribute the different items of cost among various accounts or appropriations, to know about how much the work has cost, and to distribute that cost with a refinement and an apparent accuracy that will delight the heart of the accountant. If some items are found to have been charged up in a manner inconsistent with the principles laid down by men who have never done any real constructive work, there is ground for caustic criticism, an opportunity for which is often productive of holy joy, which, however, is judiciously expressed in terms of indignation.

The object of cost records, on the other hand, is to determine how much the work is costing, and to check or correct leaks here or there, which may be due to improper organization or to ill-adapted plant or equipment. Such defects will not only add to the cost of the work, but they are frequently of such a character as to impair its quality when finished. Of course, when an intelligent system of cost records is first introduced, it cannot be expected to have an immediate effect on the particular job to which it is first applied. It will, however, indicate where improvement can be effected, and it should not be long before the system can be perfected so that the engineer can put his finger on the weak spots very quickly and correct the trouble before the record for the entire job shall have been spoiled.

Road construction and maintenance are usually paid for from public funds, and the engineer in charge of such work is almost invariably hedged about with legal restrictions and limitations, which have been placed on his authority, particularly as to the control of labor and his inability to buy in the cheapest market or to secure needed materials or supplies promptly in an emergency. It is not unnatural, under these circumstances, that he should come to regard cost records as of academic, rather than of practical, interest and value.

In the speaker's opinion, there is nothing that will operate more effectually to remove, or at least mitigate, these restrictions and limitations than an accurate, scientific presentation of the facts, with the reasons why. Even in the public service, it will be possible to select a certain number of skilled and common laborers who are fairly efficient, and if these can be grouped together and the results obtained with them compared with those of a gang of less industry and capacity, and the responsibility for low efficiency and greater cost clearly and publicly placed where it belongs, it is not unlikely that popular opinion will soon insist that the man who is responsible for results will be given a chance to produce them.

Efficiency is an impressive sort of word, and efficiency engineering sounds like a particularly dignified and useful branch of the Engineering Profession. It has naturally attracted a considerable number of men, many of whom have had little actual experience and whose capacity for destructive criticism is far more conspicuous than their ability to do constructive work. It would be a great mistake, however, to conclude that efforts to promote efficiency are not worth while. They are worth while, provided they result in a decrease of the actual unit cost of work and at the same time improve its quality. Unless this is the result, "the game is not worth the candle." If cost records do not point the way to economy without sacrifice of quality, they have only an academic value and are not worth while. If reports contain only a record of the number of contracts which have been let, the names of the contractors, and the amounts expended from each account, with the unexpended balances in each, they have no engineering value. If they are framed so as to make a favorable showing of the quantity of work done in a given time and a low cost per square yard or per mile, and at the same time omit data which might indicate that these results were accomplished at the sacrifice of quality, and if they lay emphasis on the successes and ignore the failures, they are dishonest. Mr. Lewis.

Cost records of road work should indicate as clearly as possible the proportion of the expense chargeable to:

1.—Permanent betterments, such as land purchases, grading, the improvement of lines and grades, masonry and steel bridges, and culverts. This part of the work once done may be considered permanent or sufficiently durable to outlast more than a single generation.

2.—Curbing, gutter pavement, fencing, guard-rails, wooden bridges, concrete foundation, planting, etc., all of which may need periodical repairs, but will probably last twenty years at least.

3.—The road surface, which will begin to deteriorate at once, and will need constant attention and periodical renewal.

For each piece of work the records should include:

1.—The character and first cost of the materials;

2.—Cost of delivery on the work, with kind of transportation and distance hauled;

3.—Cost of labor of all classes, and the quality of the same;

4.—Cost or present value of plant and equipment, with allowance for depreciation due to the work under construction and not previously marked off;

5.—All overhead charges, including engineering and inspection;

6.—The cost of bonds, permits, etc.;

7.—All delays due to weather, failure to receive materials, strikes, or other causes;

Mr. Lewis.

8.—A precise description of the methods used and of the surface treatment of the road;

9.—A statement as to the results obtained, the probable causes of failures or unsatisfactory work, and the means used to correct or remedy them;

10.—The manner in which the funds to pay for the work are raised, whether by cash appropriations, by the issue of bonds, with length of term and rate of interest, or by money advanced in anticipation of the collection of assessments for benefit.

Although this brief outline may have contributed nothing of value, it is hoped that it will serve the purpose of an introduction.

Mr. Tribus.

L. L. Tribus, M. Am. Soc. C. E.—The value of cost records is well illustrated in the Borough of Richmond, City of New York. In organizing its work the following queries were considered:

1. What is really needed to be done?
2. Was similar work done in preceding years necessary?
3. What had such work cost locally and in other places?
4. What should it cost?
5. How can appropriations and expenditures be controlled, so as to secure work needed and at proper cost?

Some few years ago, the City of New York as a whole felt that, in connection with its highways and sewers, there was a lack of reliable information on which the appropriating bodies could act. From its cost records, maintained for years, and practically the only ones in the city, the Borough of Richmond furnished most of the information from which appropriations were made thereafter for work throughout the Greater City.

In carrying out the plans, if a certain class of work costs less in one district than in another, an investigation is made. If the difference is large, there is some special reason for it, and the records usually show what that reason is, because conditions as to haul, temperature, and a number of other items which have an influence in the destruction or preservation of roads and sewers and in their maintenance, are known.

The speaker can testify that cost records and intelligent reports, with the giving of needed information to the men, produce results of economic value, fully within the term, "efficiency," as defined by Mr. Lewis.

Mr. Crosby.

W. W. Crosby, M. Am. Soc. C. E.—With the growing demand for efficiency in all engineering work, with the increase in attention generally to this feature, and with the recognition of the dependence on the factor of cost or expense for measuring the value of the results, it seems to have become necessary to regulate somewhat the acquisition and reporting of cost data. Up to the present, not only have

the costs of details of road work been almost as variously reported as there were reporters or details, but a similar variation has also existed in the statements of costs of the work in the aggregate or as a whole. Mr. Crosby.

For instance, if one desires to know what the total expense per mile has been to the State of Massachusetts for its completed State roads, and how that same cost unit of New York compares with the Massachusetts figures, no satisfactory, or even approximately correct, answer can be had, because of the different systems used in accounting for the road funds of the two States. The speaker had occasion, a year or more ago, to compare the cost per mile of the preliminary road surveys and plans in Maryland with those of some other State doing similar work, but he was able to find only two instances in the country where even approximate costs of this item could be had, one of these being a "post-mortem" by a special committee engaged for the purpose.

Take the simple case of a single item of road work—that of water-bound macadam. Speakers here and reporters elsewhere have variously calculated it, in some cases naming simply the price paid to a contractor; in others, where the work was done by "force account" and the machinery was rented, the rental actually paid for the machinery was included, but no depreciation, profit, or overhead charges were embraced in the figures; and, in still other instances, where perhaps the machinery was owned by the authorities, no allowances for it, nor even for the supervision, were calculated in the costs given. Yet the effort was, and is frequently, made to draw close comparisons between the resulting "cost" figures obtained by each method.

The speaker took occasion two years ago to invite attention to the importance of this matter, because of the readily apparent interest manifested in the statements of costs made by the various speakers. Further, it will probably be admitted that the satisfactory selection of a pavement to meet any local conditions will be largely affected, if not determined, by proper consideration of the cost factors. Hence the importance of accuracy in arriving at the arithmetical equivalent of these factors in the equation; and the narrower the margin, the greater the necessity becomes.

To avoid being misunderstood and considered perhaps as a "hair splitter," allow the speaker to state that exactness in this matter is not his goal, but rather "relative" accuracy. That is, he believes that almost all values are relative; that, in road matters, their dependence on other factors, such, for instance, as traffic, weather, and other conditions—impracticable of either exact determination or expression—relieves the necessity of absolute exactness, and that ordinary accuracy and uniformity are all that are necessary or desirable for purposes of satisfactory comparison, which is the end desired.

Mr. Crosby.

Therefore, in the interest of uniformity and for general benefit, attention is invited to the system for the accounting of road expenditures established in Maryland in the spring of 1912 by the speaker with the assistance of a reputable firm of expert accountants (Haskins and Sells, of New York). Although complete information in the matter could not be appropriately given on this occasion, the principles involved may be indicated briefly. They are:

First.—Charge to any item all the expenses that can be accurately determined as belonging properly to that item.

Second.—Charge to any item the cost of tools, materials, machinery, etc., consumed by that item. In the cases of tools or machinery having a life greater than their period of use for any item, then charge to that item, in lieu of depreciation, rent, interest, etc., a flat rate of 5% per month (or if preferable for any reason, 0.2% per day) for the time used on the item in question.

Third.—Such expenses as are unassignable clearly to any items, or indivisible among a group of items, are to be pro-rated among such items or groups in the proportion that the individual totals of the costs directly chargeable to such items or groups bear to the aggregate of such direct charges.

These principles can be carried into the details of the work as far as desired. If carefully applied, they seem to permit of sufficiently accurate results to enable comparisons of cost to be made intelligently, a thing now most difficult, if not impossible, between different localities not under identical authorities.

Two of the principles may seem to be simple and not new; but the speaker has found only one or two instances of even an approach to uniformity in their application, though he has searched far and wide.

The second principle, regarding charges for machinery, is probably the most novel of the three. It will not be disputed that a charge should be made for tools and machinery, but what this charge should be, and how it should be applied, may cause some discussion. The rate suggested by the speaker corresponds fairly closely with prices secured by private owners; it is simple and convenient, and to the speaker does not seem to be unfair. He admits that it will probably seem too high at first, but after experience with the relatively short life of road machinery, the desirability of keeping it in first-class condition, the length of time it is frequently idle, consideration of interest charges, obsolescence, etc., he thinks the rate suggested is wise and safe. It should be stated, perhaps, that this 5% per month is in addition to bills for minor repairs which are chargeable to the work directly.

In illustration of the application of the foregoing, the speaker submits two graphical representations of the subdivision of cost or expense into items of ordinary use—Tables 1 and 2. Table 2 shows the figures and percentages for each item or group of items in relation to the total of each group, and of the whole expense of the State Roads Commission of Maryland for 4 years (1908-'09, '10-'11), aggregating $4 250 000. Mr. Crosby.

He also submits a subdivision (Table 3), on the same basis, of the part of this expense for completed work, showing its division between the physical items ordinarily reported by the various authorities, and of general public interest.

TABLE 1.

Cost.	Administration and Legal........	Commission's (or Board's) Salaries and Expenses. Commission's (or Board's) Office Force, Salaries. Commission's (or Board's) Office Expenses. Commission's (or Board's) Counsel, Salaries, Fees and Expenses.
	Engineering, General............	Chief Engineer's Salary and Expenses. Chief Engineer's Office Employees' Salaries. Chief Engineer's Office Expenses. Chief Engineer's Instruments and Repairs. Chief Engineer's Laboratory Investigations.
	Preliminary........................	Engineers in Charge—Salary and Expenses. Survey Parties—Salary and Expenses. Office Employees' (Draftsmen, etc.) Salaries. Office Expenses, Stakes, etc.
	Construction. (Reconstruction) (Maintenance)	Engineers in Charge—Salaries and Expenses. Office Employees—Salaries. Office Expenses. Inspectors—Salaries and Expenses. Superintendents—Salaries and Expenses. Foremen, Labor, Teams, etc., Pay of Advertising. Materials Consumed, Expense for. Use of Equipment, Rental for and Repairs. Rights of Way and Damages. Advertising. Miscellaneous.
	Equipment..........................	Expense for. Transportation of and Establishment. Renewals and Depreciation. Salaries of Men in Charge of, etc.

In reference to this, let it be said that it was fully realized that seldom, if ever, are two appropriations made along identical lines, and that there will always be a necessity for accounting for the funds separately. Provision has been made for this matter, also, in the new Maryland system, and those interested in the bookkeeping are referred to the recent Report of the Roads Commission for further information on this point.

The foregoing is applicable to the records and compilations of the first cost of road work. As to the final cost of any particular piece of work, it is evident that such is the sum of the first cost and the maintenance and interest charges, or the "long-run cost."

Mr. Crosby.

TABLE 2.

				Per-cent-age.	Amount.
Total Expense $4 422 520.54.	Administration and Legal $62 910.51 1.4 per cent.		Commission Salaries and Expenses	50.33	$ 31 666.42

		Maintenance	Rental charge for average time at 5% per month equals		595.00
		Reconstruction	Rental charge for average time at 5% per month equals		800.00

NOTE.—The figures in this table are given to show the actual distribution of the total expenditures by the State Roads Commission to December 31st, 1911. The segregation into items of work done is given on pages 28, 29, 30, and 31 of the report.

The "long-run cost" the speaker conceives is made up thus: Mr. Crosby.

Long-run cost:
- Interest on first cost. (When first cost is met by bonds.)
- Sinking fund charges.
- Maintenance expenses (made up periodically along lines prescribed above for first costs).
  on:
  - Surfacing,
  - Earthwork,
  - Culverts, bridges, and drains separately, and
  - Total.

Consequently, for recording the long-run costs in Maryland, cards were designed as shown by Table 4.

Lest it be thought that the speaker has, by his suggestions, simply added work and expense to the State highway authorities for the sole purpose of furnishing engineers with more accurate data, perhaps to an inappreciably good end, he may state that, on the contrary, the revision of the accounting system of the Maryland Roads Commission has resulted in at least two direct benefits:

First.—The accounts now kept give dependable information on all points likely to arise, and give it clearly, readily, and accurately; and it has been possible to secure easily and quickly from these accounts such information on other less usual points.

Second.—The annual expense of keeping the books of the Maryland Commission has been reduced by 60% or more.

The speaker believes that the Maryland system as adopted is readily applicable to other communities, and, when thus applied, would generally be found to be beneficial. The particular point he wishes to make is that far greater uniformity than at present exists in cost recording and reporting is now, not only desirable, but necessary, if as engineers we are to be able to do our full duty.

Connected with the foregoing, concerning cost figures, the speaker has some records of expenditures and of traffic on a particular road, which records, together with some deductions or conclusions of his own, he submits, as follows:

The experimental pitch-macadam pavement on Park Heights Avenue, near Baltimore, Md., is now entering its fourth year of service. Some of the sections were completed during the summer and autumn of 1909 (Sections 1 to 9 and 19 to 27, inclusive), and others during the working season of 1910. It is thought that sufficient experience has been had with most of these sections to warrant some study of the costs, and that such a study will be profitable.

Full descriptions of the construction have already been published,* and, therefore, need not be repeated here.

* *Transactions*, Am. Soc. C. E., Vol. LXXIII, p. 74; and Vol. LXXV, p. 598.

Mr. Crosby.

TABLE 3.—SUBDIVISION OF EXPENDITURES BY THE STATE IN THE YEARS 1908

County.	Contract No.	Name of road.	Description.	Miles of road.	Preliminary surveys and plans.	CONSTRUC- Grading.	Surfacing.	Bridges and culverts.	Under-drains.
......	....	....	"State Roads".......	153.13	$11 651.93	$269 407.14	$1 042 058.56	$139 205.94	$27 432.64

......	....	....	"State Road No. 1"..	0.55	123.63	903.53	20 928.11	287.04	482.31
Totals	....	....	All kinds............	193.85	$15 398.33	$353 201.31	$1 350 471.79	$201 259.96	$33 203.93

The expenditures on the twenty-six sections of pitch-macadam, on the two surfaces treated with pitch, and on the single section treated with "Glutrin," are given in Table 5. The travel censuses, showing the character and extent of the traffic on the road, are given in Table 6.*

On account of the rebuilding of Sections 1 and 3 late in 1911 (completed early in 1912), it is thought best to omit these two sections from detailed consideration now, simply remarking that at present they are in fair condition, their defects seeming to be due, mainly, to a slight excess of pitch in spots, probably from the use of too much material as a flush coat. Section 11-A may also be omitted as of little value for deductions, as it was an emergency section pitched with an unrecorded mixture of a variety of pitches happening to be available under the exigencies of the occasion.

Let it be assumed that, in the consideration of the expenditures for the pitch work, the expenses for resurfacing the old macadam, or for putting it in condition to receive the pitch treatment, do not enter; that the unrecorded (and difficult, if not impossible, to estimate) saving from not water-binding this macadam resurfacing can be neglected; and that the maintenance expenditures on the shoulders, earth side-road, and ditches should be eliminated where separable. Then Table 7 shows the net charges on the pitch-macadam.

The charges do not include any allowances for "Overhead Expenses," "Administration," or "Engineering," but cover all expenses for materials, labor, inspection, tools, etc., on the work, rental (or allowance therefor) on machinery used, etc., and in make-up follow the lines adopted for accounting by the State Roads Commission of Maryland.†

* An explanation of the "Factors" used may be found in "A Simplification of Traffic Censuses for Purposes of Comparison." *The Surveyor* (London), March 10th, 1911, p. 364: or *Municipal Engineering*, March, 1911, p. 167.

† First Report, State Roads Commissioner of Maryland for 1908-09-10-11.

Mr. Crosby.

Roads Commission of Maryland for Completed Roads to 1912, Inclusive.

TION.				Rights of way and damages.	Total, including rights of way and damages.	Administration, legal and general engineering expenses.	Total cost of road.	Cost per mile.
Inspection and superintendence.	Miscellaneous.	Total.	Cost per mile.					
$37 538.25	$7 321.39	$1 534 615.85	$10 021.65	$3 032.09	$1 537 647.94	$70 088.24	$1 607 736.18	$10 499.16

2 124.90	212.56	164 506.24	12 387.52	1 915.85	166 422.09	7 582.93	174 005.02	13 102.79
736.72	51.48	23 512.82	42 750.58	......	23 512.82	1 077.08	24 589.90	44 708.91
$52 241.25	$8 820.94	$2 014 597.51	$10 387.40	$4 947.94	$2 019 545.45	$91 938.14	$2 111 483.59	$10 892.36

The following conclusions are drawn from these data and the speaker's experience with the work and its results:

Section 29, having been newly resurfaced with a fairly hard limestone water-bound macadam in 1909, and having shown by the summer of 1910 a tendency to serious deterioration under the travel on it, and since the latter date having been treated (as apparently necessary) with "Glutrin," and now being in fully as good condition as before the treatment was begun, the speaker is of the opinion that:

(*a*) A 12-ft., water-bound, limestone macadam will not support successfully travel aggregating 400 units per average day of 10 hours, and where 60% of the total travel is that of motors.

(*b*) Such a road surface can be made to sustain such travel, with physical satisfaction, by treating it with "Glutrin."

(*c*) Such a road surface can be made to sustain such travel, with physical satisfaction, by giving it a surface treatment of "cut-back Texas asphalt" (Section 28).

(*d*) An 18-ft., water-bound, trap rock macadam is incapable of sustaining, without serious deterioration in a few months, travel aggregating 2 500 units per average day of 10 hours, and where 90% of the total travel is that of motors.

(*e*) The surface treatment of such a road with a proper cut-back sludge asphalt, or a proper compound of water-gas tar, will enable it to sustain such travel, with physical satisfaction (Sections 15 and 16).

(*f*) A 24-ft. pitch-macadam, of either limestone or trap rock, will sustain, with at least physical satisfaction, travel aggregating as many as 15 000 units per average day of 10 hours, and when more than 95% of the total travel is that of motors (Sections 4 and 5).

(*g*) A 14-ft. pitch-macadam, of either limestone or trap rock, will sustain, with at least physical satisfaction, travel aggregating 5 000

Mr. Crosby.

units per average day of 10 hours, and when less than 15% of the total travel is that of horse-drawn vehicles (Sections 17 to 27, inclusive). Mr. Crosby.

(*h*) The present indications are that the use of pitch in quantities of more than 1¾ gal. per sq. yd., in the construction of pitch-macadam, where the upper course of the macadam is to be 3 in. thick after compaction, is generally inadvisable.

(*i*) The use of a flush coat, except possibly in the cases of pitches having unusual stability under the application of heat, is inadvisable in the construction of pitch-macadam, unless the proportion of horse-drawn travel to motor travel is considerably higher than in this case.

(*j*) With the use of materials susceptible to heat, or fairly so—such as most tars—the application of the pitch to the rolled stone can safely be stopped at a line parallel to and 1 ft. within the edges of the stone, and reliance can be felt that this border of the macadam, later, will be properly bound by the flow of the pitch under heat and travel.

(*k*) With the use of asphaltic or blown-oil pitches, having a "penetration" at normal temperatures harder than 150, the application of the pitch should be made fully to the edges of the rolled stone.

(*l*) The requisite penetration of the pitch into the rolled stone is obtained when the pitch reaches to the bottom of the average sized stone in the course penetrated.

(*m*) Success in the construction of pitch-macadam depends primarily on the proper compaction of the macadam particles, and is directly proportional to the success in rolling the macadam before spreading the pitch.

(*n*) The use of sand on top of the pitch is open to grave objections, and the value of its use before spreading the pitch is questionable, clean stone chips of small gravel, free from particles which will not pass ⅛-in. mesh being preferable.

(*o*) With the use of a proper pitch, there is no material advantage in closing the finished pitch-macadam to travel for a period after its construction, provided the adhesion of tires to the surface is prevented by watering, spreading an excess of grit, or by other means.

(*p*) For pitch-macadam, a pitch, to be satisfactory, should possess at least the following characteristics:

(1) It should flow freely, though not excessively so, under the conditions of application.

(2) It should show, after evaporation at 105° cent. for 21 hours (20 grams in 3½-in. dish), a penetration of not less than 10 at 4° cent., and not more than 100 at 25° cent. (No. 2 needle, 100 grams, 5 sec.).

(3) The naphtha-soluble portions of the pitch, when evaporated on glass, should show themselves to be decidedly adhesive.

Mr. Crosby.

§ Reconstructed, 1911.
‖ Chips hauled and spread on account of bleeding.
¶ Rolling in No. 2 stone and chipping.

is the 14-ft. width economical where the travel exceeds 2 000 units and the proportion of motor travel is more than 80% of the total.

(*s*) Where high-speed motor travel forms a large proportion of the total, the unit width of travel lines should be considered as 9 or 10 ft., instead of 7 or 8 ft., as heretofore, because of the greater clearance required for the safe passing of the units of such travel.

Further economic conclusions seem to be rather premature at this time, and such, including a deduction concerning the possible advantage of using an excess of pitch during construction in order to prolong the life of the pitch-macadam, and perhaps in the end to reduce the cost, it would seem preferable to defer for two or three years.

Mr. Crosby.

(a) Omitted from further consideration at this time because of recent construction. (b) From records; other units, approximations.

GEORGE W. TILLSON, M. AM. SOC. C. E.—In these days of increase in the values of labor and materials, and the prospect that they will continue to increase, it certainly is incumbent on those who utilize these two elements to know that it is done to the best advantage, to see that when they are combined and produce a result, that the result has not cost more than it should. It is not enough for a contractor to know whether a job is a paying one, or a losing one; he should know whether or not every part of his contract is being carried out on a paying basis. Mr. Tillson.

It seems to the speaker that, as Mr. Lewis has said, a great deal of the work which has been done on cost records and reports is more in the nature of accounting than of cost-keeping. Construction work is not done for the purpose of allowing some one to get up an elaborate system of accounting, strange as it may seem to some accountants. The cost-keeping, or the accounting, should be carried on in such a way as to give detailed information about the work, and the important point is to analyze the situation properly into its different elements. By an analysis a contractor can determine very quickly whether a contract is or is not a paying one, if properly carried out. After he does that, he can establish a system of costs for the different movements in carrying out the work. In keeping account of the cost of items, it is possible to go too far; it is possible to build such an elaborate system of cost-keeping that no general result is obtained.

In the Bureau of Highways, in the Borough of Brooklyn, a very good system has been in use for several years, by which it is possible to show the cost of every item in connection with the work in that Bureau. The following from the report of the Bureau for 1911 shows the system of cost-keeping used for the repairs of asphalt pavements, and how the same has been analyzed and subdivided into different items:

ANALYSIS OF MAINTENANCE COSTS.

General and Special Costs.	Wearing Surface. Per Box. (9.3 cu. ft.)
Superintendence	$0.056
Superintendent's auto	0.051
Repairs to plant	0.128
Repairs to tools	0.108
Dumping privilege	0.094
Coal	0.092
Wood	0.046
Misc. supplies, etc.	0.052
Depreciation	0.095
Interest	0.047
Rent	0.033
Carried forward	$0.802

Mr. Tillson.

Material Costs.		Wearing Surface. Per Box. (9.3 cu. ft.)
Brought forward		$0.802
Asphalt	$1.220	
Residuum oil	0.033	
Stone dust	0.195	
Asphalt sand	0.208	
		1.656
Labor and Trucking Costs.		
Plant labor	$0.423	
Street labor	1.694	
Trucking	0.556	
		2.673
Total		$5.131
Cost per cubic foot		$0.552

The total for the 9.3 cu. ft. of material is $\$5.13\frac{1}{10}$ or $55\frac{2}{10}$ cents per cu. ft. It takes about 1.75 cu. ft. for 1 sq. yd. of asphalt 2 in. thick. If the contractor has his work divided on some such principle as that, he can tell absolutely what each item has cost. By daily reports as to the quantity of work done by his different gangs in different parts of the city, he is able every morning to tell whether each man is coming up to his idea of what he should do, or what the records of previous years had shown that men and teams could do.

Mr. Connell.

William H. Connell, Assoc. M. Am. Soc. C. E.—If engineers wish to keep abreast of the times and attain the highest point of efficiency in their work, cost records and reports are essential.

The moral effect alone on an organization is justification for keeping unit cost records. This is illustrated by the pride aroused in the men in connection with their work. The natural instinct of man is to excel in his undertakings, but it must be remembered that men must be led and not driven, and in order to get the best out of them their interest in their work must be aroused, and they must be impressed with a sense of their responsibility. There is no better way of doing this than by the friendly competition resulting from unit cost records. Men are naturally ambitious—this is clearly illustrated in pastimes and sports, whether it be shooting marbles, pitching quoits, playing baseball, or any other form of amusement that brings out competition—all want to excel, and will work hard to do so; one reason is because they understand what they are doing and are interested; the other is because their ambition is aroused through competition, with the result that they will do the best they can. This same situation should exist in all classes of work. There is no man—no matter how lowly he may be, or whatever may be the nature of his work—whose interest cannot be aroused by impressing him with

a sense of his responsibility and showing him wherein the competition lies in connection with his work. Men are often lackadaisical about their work because they do not understand just what part they are playing, and, consequently, have no particular interest in it, whereas if they understood more about the relationship of their work to the undertaking as a whole, their interest would be aroused and they would appreciate their responsibility. The only difference between amusements and work, in bringing out competition, is that in the first instance the man understands the game, has a part in it, and plays it for all it is worth; while in the latter instance he does not understand the work or his part in it; consequently, his interest is not aroused and he does not put forth his greatest efforts, which is not only a loss to him, but to his employers. Therefore, anything that can be done to arouse the interest of the men in their work and bring about friendly competition is of inestimable value, and nothing will do more to produce this result than unit cost records. Mr. Connell.

Cost records are probably the principal means of control of work, and unit cost records are an analysis of cost records, and bring out the weak and strong spots in a working organization. As already stated, unit cost records are simply a modern system of records designed to keep the work and organization up to the highest point of efficiency. Such records are also of great value in comparing costs of similar work in different industrial establishments, municipalities, public works departments, etc. It has often been said that unit cost records do not mean anything on account of the different conditions under which work is done, the difference in wages, labor hours, etc. Of course they are of no value, and are only misleading, unless they are given in detail, but if this is done, and if they are properly compiled, such records are comparable with cost records of similar work in other establishments and localities, and are invaluable. Only a few months ago, the budget for the Highway Bureau of Philadelphia, Pa., for 1913, was made up largely by proportioning the unit cost of similar work in the Borough of The Bronx, New York City. This was made necessary by the absolute lack of cost records or reliable data of any description in connection with the work coming under the jurisdiction of the Bureau. It is impossible to make up an intelligent estimate without the aid of cost records, and it is equally impossible to determine whether all branches of the work are being carried on in an economical manner in the absence of unit cost records.

There seems to be a rather general impression that the necessary job orders, time sheets, material reports, and progress reports which the foreman is required to handle, are apt to confuse him and, consequently, decrease rather than increase the efficiency of his work. This is not so; on the contrary, they tend to develop the foreman, awaken

Mr. Connell.

his interest, and, in many instances, make a new man of him. Why? Simply because he is placed on his mettle, taken in, to a certain extent, on the financial and business end, made a more important factor in the organization, and, consequently, his work means more to him than the mere physical results. We underestimate the ability of the working classes. A large majority of them, of course, have not had the advantages of an education, but they are all capable of being developed, and are simply waiting for opportunities. Just because a foreman never made up modern cost record reports is no reason why he cannot do it; naturally, it would be confusing in the beginning, and he would make a great many mistakes, but before long, in all probability, he would be suggesting improvements in the form of the reports, which would be better suited to the conditions.

Cost records and reports are invaluable guides in the conduct of work of whatever nature, and must not be underestimated if engineers wish to carry on their work in an efficient and economical manner.

Mr. Blanchard.

A. H. BLANCHARD, M. AM. SOC. C. E.—Labor is an element of road costs which demands careful consideration. Many instances may be cited where equally competent engineering supervision governed work of the same character and where the costs of materials were the same, but where the quality of labor and the number of working hours were not equivalent, and hence the total prices varied to a remarkable extent. The speaker has been connected with work where the hours were the same but, due to incompetency on one hand and ability on the other, the unit labor cost in the former was three times that in the latter case. It is evident that complete data relative to labor should be given, otherwise erroneous deductions will be made.

In connection with construction and maintenance work accomplished under the day-labor system in State, county, and municipal departments, many labor costs are given. Here, without doubt, one finds the greatest variation in the quality of the labor. Poor administration, and political interference with the personnel of the labor organization, are mainly accountable for the marked difference in quality which exists.

Mr. Durham.

H. W. DURHAM, M. AM. SOC. C. E.—One essential feature in regard to cost records is the importance of not letting the keeping of such records become the end instead of the means; undue emphasis should not be placed on the machinery of cost-keeping. Frequently, the matter of recording becomes so laborious, the organization doing it so great, that it is really regarded as the ultimate end to be sought, and, by the time the tabulations are made and the costs worked up, the information obtained is of no particular value on the immediate work.

For efficiency, cost records must be kept so that the results can be compiled at short intervals of time, and give some comparison as to

Mr. Durham.

the items of the work immediately under consideration, in order that it can be seen instantly whether or not the work is going on properly. It should also be borne in mind that detailed cost records may not be of such great value to the engineer supervising contract work as they would be were he directly handling by day's labor an organization and could point out to the individual gangs, where one excelled another.

For a city or municipal organization, there are no better general methods than those which have been adopted by the Board of Water Supply of New York City, the Public Service Commission, and similar organizations.

Details as to how the records should be kept, what charges should be made, overhead plant charges, etc., are matters which concern all engineers. It is not only necessary to know the price of the materials that are being actually used, but what is being paid for labor and other items, the charge for depreciation on plant, overhead charges, and matters of like character.

Unless such correct distribution of the details of cost is made, the records become worse than useless and allow wrong inferences to be drawn, as in a case of certain road work with which the speaker is familiar, where an excessive unit cost per mile, when analyzed, was shown to be largely due to the inclusion of the entire first cost of the plant used.

Mr. Wilcock.

FREDERICK WILCOCK, ASSOC. M. AM. SOC. C. E.—Determination of engineering costs is important in the public service. Such costs, if compared periodically with the contractors' requisitions for payment for work done, and published for the engineers, are an inducement to eliminate the inefficient members of the corps as soon as possible, and tend to improve the standards of the younger members of the Profession. The elimination is made usually at the end of the probationary period customarily required by civil service rules. This opinion is drawn from observation of construction work in New York City.

(3) DESIGN OF HIGHWAY SYSTEMS.

BY MESSRS. JEAN DE PULLIGNY, BERTRAM BREWER, NELSON P. LEWIS, JAMES OWEN, AMOS SCHAEFFER, J. W. HOWARD, C. E. CARTER, F. O. WHITNEY, AND A. H. BLANCHARD.

Mr. Pulligny. JEAN DE PULLIGNY, M. AM. SOC. C. E.* (by letter).—The writer will not undertake to decide what a highway system ought to be, but will outline briefly what the French highway system is, in the belief that such a system, with appropriate modifications, might furnish a basis for an American centralized State system of highways.

THE FRENCH ROAD SYSTEM.

The following remarks do not apply primarily to the National Main Highways which connect Paris with the large cities and the frontiers, and are constructed and maintained by the Central Government. These main highways (*Routes Nationales*), were built more than 150 years ago—when scarcely any roads were to be found in other countries—for carrying the Royal mail.

Their total length is about 24 000 miles, and the annual appropriation for their reconstruction and maintenance is $6 500 000. The total width of these main highways is 43 ft. 4 in., 53 ft. 4 in., or 81 ft. 3 in., according to classes, including lateral ditches of 6 ft. 8 in. and a central metaled roadway of 16 ft. 8 in., 20 ft., or 25 ft. 6 in., generally constructed of water-bound macadam which is tarred or oiled in summer. On the sides of most of these roads trees are planted, and form graceful avenues, of which many are old and quite beautiful.

The cost of building and maintaining these roads is rather high. It varies, of course, in different parts of France, and, in the past, it has varied according to the times. The general expense for the 24 000 miles of main roads has been about $300 000 000, or an average of $12 600 per mile. The cost of maintenance is about $6 500 000 yearly, averaging $270 per mile. If the average highway of this kind is considered as being about 20 yd. wide, including ditches, the prices per square yard would be $0.35 for construction and $0.00765 for maintenance. If the width is taken at only 15½ yd., the ditches excluded, the maintenance cost would be about $0.0099 per sq. yd.

These highways played a very important part in National activity in France before railroads were constructed. Nowadays, it is believed by the writer, they are less important than the other roads of the

* Most of the information in this discussion has been collected expressly for American engineers by the noted road expert, M. Le Gavrian, of Versailles, *Ingenieur des Ponts et Chaussées*, and Assistant General Secretary of the Permanent International Association of Road Congresses.

country, which amount to 339 500 miles in length and require an annual expenditure of $37 400 000. These roads include mainly *Chemins Vicinaux de Grande Communication,* connecting the cities and villages, and the less important *Chemins Vicinaux Ordinaires,* which connect farms with the next village or the nearest city. Mr. Pulligny.

The total widths of the *Chemins de Grande Communication* are 23 ft. 4 in., 26 ft. 8 in., 33 ft. 4 in., or 43 ft. 4 in., according to the class. These widths include lateral ditches of 3 ft. 4 in. or 5 ft., and a central metaled roadway of 13 ft. 4 in. or 16 ft. 8 in. In the case of the simple *Chemins Ordinaires,* the total width is 20 ft. with ditches of 3 ft. 4 in., and a central roadway of only 10 ft. As to the *Chemins Ruraux,* their dimensions may be still less, and sometimes there are no ditches.

On the National highways the maximum grade is 3 in 100, and the minimum radius of curves is 150 ft. On the other roads the maximum grade is 5 in 100, and the minimum radius of curves is 100 ft. It is important not to increase these grades. On a 3 in 100 grade the effort in hauling a load is about twice as much as that required on a good level road, and on a 5 in 100 grade, the effort is nearly tripled. If the length of such an incline is short, the horses may give the needed supplementary effort, and no reduction of the load is necessary; but if the slope is steep for a long distance, such a reduction is unavoidable. As it applies to the total load, and as the dead load cannot be reduced, it is understood that the useful load is reduced proportionally. Motor trucks are affected as much as horses in such cases, and perhaps more.

Before returning to the subject of main highways, the opinion is expressed that some system of Federal or State main highways, built and maintained by Federal or State engineers, may certainly be justified in the United States, where there is no lack of able engineers, centralized authority, or money. The difficulty is to provide the other system of ordinary roads with able engineers, with centralized authority, and with sufficient yearly appropriations. It is this phase of the subject which will be further considered.

Technical Organization of the French Road System.

France is not so strictly centralized as it is believed to be by many engineers. It is divided into 86 territorial units, called *Departements,* the average area of each of which would be about equal to 3 counties of the State of New York. Hence, New York, having 61 counties, would make 20 French *Departements.* The 86 *Departements* (plus Belfort Territory) are divided into 275 *Arrondissements* (average by *Departement,* $\frac{275}{86} = 3.2$). The 275 *Arrondissements* are divided into 2 325 *Cantons*

Mr. Pulligny. (average by *Departement*, $\frac{2\,325}{86} = 27$; average by *Arrondissement*, $\frac{2\,325}{275} = 8.4$); and the 2 325 *Cantons* are divided into 36 222 *Communes* (average by *Departement*, $\frac{36\,222}{86} = 420$). The gross area of France is 207 000 sq. miles. The average area of an *Arrondissement*, therefore, is $\frac{207\,000}{275} = 750$ sq. miles, being about the average area of a New York county. The area of New York State is 49 204 sq. miles, and the average area of each county is $\frac{49\,204}{61} = 800$ sq. miles.

Each Department is also a unit for several public services, and, furthermore, is a political unit. It has a Governor, appointed by the Central Government, called a *Prefet*, and an elective body called the *Conseil Général*. It has also certain revenues produced by taxes, the appropriation of which is decided by the *Conseil Général*.

All the road system of *Chemins Vicinaux* is managed by the *Prefet*, and the expenditure is voted by the *Conseil Général*, the Central Government having practically nothing to do with it.

The *Prefet*, of course, does not manage the road system himself, but through a centralized body of competent technical men. In about half the Departments the work has been entrusted by the *Conseils Généraux* to the body of Government Engineers—*Ingenieurs des Ponts et Chaussées*—to which the writer has the honor to belong. These roads comprise only a small part of their work. They also have in charge the National Main Highways and the various civil engineering works which are administered by the French Government, including all the inland navigation works, canals and canalized rivers, all the ports, docks, harbors, sea shores, and light-houses, and the close inspection maintained by the French Government over the railroads, with reference to safety, regularity, and rates, and also to secure a proper maintenance of the railroad property which is only entrusted to the railroad companies for a definite period, at the expiration of which, such property will be returned to the Government.

In the other half of the Departments (exactly forty-six) special technical bodies have been organized, which are, of course, quite outside of politics. They include a chief road engineer, residing at the Capital of the Department, near the *Prefet*, and having charge of all the *Chemins Vicinaux* of the *Departement*.

Each *Departement* is divided into three or four political districts headed by a *Sous Prefet*, and called an *Arrondissement*. In each Capital of each district there resides a district road engineer who

Mr. Pulligny.

is under the orders of the chief road engineer and has charge of all the *Chemins Vicinaux* of the *Arrondissement.*

Each *Arrondissement* is divided into eight or nine judicial districts, named *Cantons,* each of which also has its small Capital, in which resides an assistant road engineer who has charge of all *Chemins Vicinaux* included in the *Canton.* He is under the orders of the district road engineer.

Finally, all roads in a *Canton* are divided into sections, each having an average length of 4 miles, and on each of these sections the celebrated French *Cantonnier,* or road patrolman, works constantly with his pick-axe, shovel, shrub, and wheel-barrow. These *Cantonniers* are under the orders of the assistant road engineer. A few of them have shorter sections, and they look after the work of their neighbors, as foremen (*Chefs Cantonniers*). The Cantonniers are simple laborers, generally of agricultural training, and are not required to have any special knowledge in order to enter the service. They are only expected to be of respectable behavior, to be able to read and write, and to be steady and trustworthy workers.

It is evident that every square yard of French roads is under the permanent care of a patrolman, of a chief patrolman, of an assistant road engineer, of a district road engineer, and of a chief road engineer. All these men form a hierarchy, with the *Prefet* as the head. Any complaint by the people, or their representatives, to the *Prefet* is properly attended to.

All members of the road service, from the patrolman to the chief engineer, work under a civil service law. When they have once entered the service, they can only be dismissed in case of serious misbehavior. They are promoted at regular intervals, with better pay, and when they retire, after thirty years' work, they get an old age pension.

Most of the patrolmen lack sufficient knowledge to become assistant engineers. The latter are recruited by public competitive examinations, taking place every two or three years, from among young men who have studied, by themselves or in school, the necessary subjects such as the elements of mathematics, surveying, drafting, designing, and road construction and maintenance. The boys employed as helpers for drafting, designing, and surveying, in the offices of road engineers, also generally undergo these public examinations. Their practical experience serves them well, and most of them succeed. The district engineers are generally chosen from among the most able and experienced of the assistant engineers who have had many years of service. The chief engineer for the whole Department may have been previously a district engineer, but it is not obligatory. In some cases he was formerly a civil engineer, a graduate from one of the principal schools, an architect, or an *Ingenieur des Ponts et Chaussées.*

Mr. Pulligny.

Table 1 shows the number of chief, district, and assistant road engineers in each of the 46 Departments where a special road service has been organized.

As examples, statements will be given concerning the salaries of the road engineers and assistants in two Departments: In Seine-et-Marne (population = 358 325; area = 2 300 sq. miles) the service is entrusted to the *Ingenieurs des Ponts et Chaussées;* in Seine-et-Oise (population = 707 325; area = 2 170 sq. miles) there is a special service of departmental road engineers.

Mr. Pulligny.

Department of Seine-et-Marne.

(Road Service Entrusted to the Government Civil Engineers.)

The body of Government Civil Engineers (*Ponts et Chaussées*) was created on February 1st, 1716, and the *École des Ponts et Chaussées,* for the education of such engineers, was founded in 1750.

The classes and salaries in the body of the *Ponts et Chaussées* are as follows:

	Annual salary.	
Inspecteur Général	$2 900 to $3 400	according to seniority.
Ingénieur en Chef	1 900 to 2 300	" " "
Ingénieur Ordinaire	965 to 1 350	" " "

In addition to their Government work, these engineers are allowed to work for departments, cities, chambers of commerce, etc. From this and from other supplements given by the State itself nearly all engineers earn at least $200 yearly. Many earn more, and the supplements of a few equal or exceed their State salary.

The State salaries of their assistants are as follows:

Conducteurs (Assistant Engineers), $425 to $965 per annum, according to seniority.

Commis (Office and Field Graduate Assistants), $280 to $675 per annum, according to seniority.

After 30 years of employment, all engineers and assistants are granted an old age pension of about one-half of the highest salary they have obtained. Besides their State salary and supplements, the engineers and their assistants receive the following fees for their departmental road service:

		Annual fee.
Ponts et Chaussées:	Chief Engineer	$1 150
	District Engineer	575

Conducteurs (Assistant Engineers)	$123 to $192,	according to seniority.
Office Assistants: Head clerks	210 to 385	" " "
Typewriters and field and office assistants	50 to 150	" " "

The patrolmen are special for the Departmental Road Service. Their monthly salary is as follows, according to seniority:

Chief Patrolman	$25 to $27
Patrolman	19 to 21

When these officials are ordered to travel outside the limits of the city in which they reside, they receive traveling expenses.

During 1912 the total salaries, traveling, and sundry expenses for the road officials, including patrolmen, in the Department of Seine-et-Marne, amounted to $28 000.

Mr. Pulligny.

DEPARTMENT OF SEINE-ET-OISE.

(Special Departmental Road Service.)

The salaries and old age pensions after 30 years' service are as follows:

	Annual salary.			Annual pension after 30 years' service.
Agent Voyer en Chef (Chief Road Engineer)			$1 920	$1 440
District Engineer	$960	to	1 100	825
Assistant Engineer	480	to	850	640
Office and Field Graduate Assistants	280	to	575	430
	Monthly salary.			
Chief Patrolman	$22	to	$25	121
Patrolman	16.50	to	19	100

Many employees also receive various supplements for the high cost of living in certain cities, help to large families, extra work, traveling expenses, etc.

The total of these expenses for the office staff in the Department during 1911 was $10 400. The total expense for patrolmen and chief patrolmen, including all sundry expenses, was $72 500.

These two Departments are near Paris, where the cost of living and all salaries are high. In many other Departments, the salaries would be smaller by 10 and, in a few, by 25 per cent.

The total expense for the *Chemins Vicinaux* of all classes during 1910 amounted to $37 500 000, as follows:

Regular maintenance	$26 355 000
General repairs	2 100 000
Building new roads	4 420 000
Land acquisitions	890 000
Sundry expenses	335 000
Salaries and general expenses	3 400 000
Total	$37 500 000

ADMINISTRATIVE AND FINANCIAL ORGANIZATION OF THE FRENCH ROAD SYSTEM.

The engineers of the road service not only build new roads and maintain existing ones, but take an important part in the administrative and financial working of the road system.

The assistant engineers walk nearly all day on the roads of their district, or they may ride on a bicycle, in a carriage, or in an automobile. They constantly meet the elected Mayors of the small towns, and they know all the needs of the people. Knowing also approximately the available resources for the coming year, they prepare, for each

township and for each road of their district, a scheme for maintenance expenses and for the building of new roads. They send their reports to the district engineer who sums them up and makes any changes he deems necessary. Mr. Pulligny.

All the district engineers forward their reports to the chief engineer, who designs a general scheme for the maintenance and building of new roads in the whole Department. Each town or village has its small elective body which is called to deliberate on the road work and on the expense in which it is concerned. A Bill for this scheme is then discussed by the Department's Legislature in its annual session, and may undergo some changes. The appropriation is finally voted, and the works are then carried out with no more intervention on the part of the political representatives, the road engineers acting only under the authority of the *Prefet*. The expense is levied on the town or village as a public tax, even if the people do not approve of it.

The *Chemins Vicinaux*, thus taken care of by the Department, are the *Chemins de Grande Communication* which connect two or more towns or villages. In such cases it is admitted that the maintenance of the roads must not be entrusted to the townships, because one town might do its share of the work and suffer because the other town would not do the same; therefore, the money is provided by the town taxes, but the direction of the work is assured by the Department.

The construction of new *Chemins de Grande Communication* is undertaken by the Department for the same reason, but, in this case, there is an important difference as to the origin of the funds. Instead of providing all the money from municipal revenues, the towns only give a part of it, and the remainder is appropriated by the Department from its share of certain taxes, the amount of which is divided between the Central State, the Department, and the towns. The sharing of the expense between the town and the Department is provided in accord with definite rules, in which both the needs of the township and its resources are considered.

The total revenue produced by certain taxes is supposed to be an index of the comparative wealth of the townships, and the area of their district is considered as a measure of their needs for roads. The revenue being divided by the area, the quotient is considered as an index number by which the townships are classified, and, for a certain index number, they may receive a definite percentage of help from the Department, as high as 85% for a very poor township with a very wide area needing very long roads.

A similar classification is made in the Departments on the same double basis of wealth and area, and an annual appropriation from the Central Government's fund is divided between the Departments as a National aid for the construction of their roads. This appropriation

Mr. Pulligny. amounted to only $2 000 000 in 1910. It has been larger in certain other years.

Such is the technical, administrative, and financial system, and it has worked satisfactorily in France for nearly a century. It only applies to the *Chemins Vicinaux de Grande Communication* which concern two or more towns or villages.

As for the *Chemins Vicinaux Ordinaires, Chemins Ruraux,* and *Rues* (streets) which concern only one town or village, the Mayors are free to build and maintain these roads out of the municipal funds, as they wish. In fact, all the villages and small towns voluntarily entrust their road work to the assistant road engineer, whom they see daily, and he does it for a small fee. If a town is more important, if it has a few municipal works of sewerage, water, gas, or electricity, to be looked after, besides the road work, a special engineer is appointed and takes care of the whole. If a city is still more important, one or more municipal engineering services are organized. The municipal engineering services of the City of Paris are extremely complete, and their organization is most remarkable, from every point of view.

A few words may be devoted to two other divisions made by the laws of the past in reference to the French roads, namely, the *Routes Departementales* and the *Chemins d'Interet Commun,* which are nothing more than types of *Chemins de Grande Communication.*

The difference in names carries a few changes in the rules governing the management of these roads and the corresponding funds. These changes are not directed toward simplicity. For many years the tendency in all Departments has been to have only one class of roads, the *Chemins de Grande Communication.* No more *Chemins d'Interet Commun* are created, and every year some *Routes Departementales* are dropped from the official lists, and are afterward considered as *Chemins de Grande Communication.* The length of the *Routes Departementales* has decreased from 29 500 miles, in 1869, to 8 100 at the present time.

On January 1st, 1911, the 395 729 miles of *Chemins Vicinaux* were distributed as shown in Table 2.

As previously stated, there are also 8 100 miles of *Routes Departementales* and 24 000 miles of *Routes Nationales,* forming a grand total of 428 000 miles of roads of all classes.

The building and maintenance expenses of the *Chemins Vicinaux* have varied according to time and place, but the figures in Table 3 give an idea of what they usually cost. The lengths considered include only the roads accepted or under construction.

For comparison the figures relating to the *Routes Nationales* have been reproduced, and also some for the *Routes Departementales.*

The total length of French roads is nearly 372 000 miles, and their total cost may be considered roughly as more than $1 500 000 000. The

difference between these 372 000 miles and the total of 428 000 previously given, results from the omission from Table 3 of the 56 240 miles which have only been designed. There are also about 155 000 miles of farm roads, with or without ditches, metaled roadway, and maintenance. Mr. Pulligny.

TABLE 2.—CHEMINS VICINAUX.

Condition.	DE GRANDE COMMUNICATION.	D'INTERET COMMUN.	ORDINAIRES.	TOTALS.
	Miles.	Miles.	Miles.	Miles.
Accepted and regularly maintained............	107 000	47 200	178 000	332 200
Under construction......	287	302	6 700	7 289
Only designed...........	970	1 770	58 500	56 240

TABLE 3.—USUAL COST OF FRENCH ROADS.

Classes.	Total length, in miles.	Average Width, in Yards: Ditches included.	Average Width, in Yards: Ditches excluded.	Approximate Cost of: Building: Total expense.	Building: Per mile.	Building: Per square yard, ditches included.	Annual Maintenance: Total expense.	Annual Maintenance: Per mile.	Annual Maintenance: Per square yard, ditches excluded.
Routes Nationales........	23 800	20	15⅛	$300 000 000	$12 600	$0.36	$6 500 000	$270	$0.0099
Routes Departementales.	8 100	14	11	63 000 000	7 750	0.32	1 500 000	185	0,0095
Chemins Vicinaux de Grande Communication.	107 300	10¾	8½	665 000 000	6 200	0.33	16 900 000	157	0.0105
D'Interet Commun.......	47 500	10	7½	178 000 000	3 750	0.21	6 000 000	126	0.0095
Ordinaires...............	184 700	9	6⅛	457 000 000	2 470	0.16	14 500 000	78	0,0068
Totals................	371 700	....	....	$1 663 000 000	....	....	$45 400 000	....	......

The annual maintenance of the 372 000 miles of regular roads requires nearly $45 500 000, the share of the Central Government being $6 500 000 and that of the 86 *Departements* nearly $39 000 000. This shows a contribution of about $1 per head of population.

For comparison, a few rough figures are given in Table 4 in regard to the other means of public transportation in France, long-distance railroads, local railroads, road cars, canalized rivers, and canals.

Mr. Pulligny.

TABLE 4.—LENGTH, COST, ETC., OF FRENCH RAILROADS, TRAMWAYS, CANALIZED RIVERS, AND CANALS.

	Total building expense.	Total length, in miles.	Average Cost: Building per mile.	Annual Maintenance. Total.	Per mile.
Long-distance railroads...	$3 100 000 000	25 000	$124 000	$31 000 000	$1 240
Local railroads...........	370 000 000	5 200	71 000	1 610 000	310
Tramways (road cars)....		5 750

Mr. Brewer.

BERTRAM BREWER, M. AM. SOC. C. E.—In Massachusetts there are Boards of Survey which, to a certain extent, may control the development of the roads in any municipality. Every town has the privilege of accepting a State law which provides for such a Board, and, in many cases, the cities, to which this general law does not apply, have secured from the Legislature a special act governing their own particular cases. These laws vary somewhat, but they are all framed with one end in view, namely, the creation of a board which may guide and, as far as is legally possible, control the design of the various municipal highways or systems of highways.

In the City of Waltham these highways are classed as main thoroughfares or interurban roads, local thoroughfares or parkways, and, thirdly, residential streets. It is the duty of the Local Board to record

Mr. Brewer.

plans, either by adopting the petitioner's designs or by making its own, which will secure a system of highways to fit the peculiar needs of the place. Much can be, and has been, done toward the improvement of municipal street systems. It is a fair question, however, as to whether or not great systems of highways, either State or National, can be built up in this way, though local boards are often broader-minded than one would expect, especially if they are intelligently and tactfully advised by a competent engineer.

The speaker wants to make a plea for more consideration, on the part of engineers, for some of those things which cannot be determined altogether by the transit; a consideration of those factors which make for more permanent values, not only in the road itself, but in the abutting property; a consideration of the fact that, as Stevenson puts it, "every year, as a road goes on, more and more people are found to use it and others are raised up to repair and perpetuate it and keep it alive"; and, he might have added, 'to build beside it".

Two factors which contribute to this permanency of values, not only to the road itself, but also to its surroundings, are often ignored, namely, adequate drainage and the development of suitable and attractive building sites. The engineer fails to remember that drainage of the road itself is no more essential than a location which will admit of inexpensive and adequate drainage of the whole territory which it serves. It is time also for him to remember that even the larger systems of highways will be built on sooner or later, and the character of the building sites which they are destined to develop and serve, on account of appropriate and attractive location, is becoming appreciated more and more by the people of the United States. Highways of any sort cannot be designed and engineered in the same way as a railroad system, for itself and its own particular uses alone. Its surroundings are as important as itself, and too often are entirely overlooked.

Mr. Lewis.

Nelson P. Lewis, M. Am. Soc. C. E.—Highways are intended primarily to supply means of communication and transportation, to permit travel from place to place with a minimum of effort and resistance and in the least possible time. The importance of an intelligent and rational system of roads has not been appreciated. Much attention has been devoted to details of construction, and properly, but there has been too little regard for the real purpose of the highway. Much has been said and written about the planning of the streets of towns, but little about the design of the system of rural highways leading to and from towns and cities, and yet the difference is largely one of scale, rather than of principle. The considerations which should control the development of a system of highways in city, county, or state, have been quite generally disregarded, the chief aim usually having been simply to afford access to the abutting plot, estate, or farm.

Mr. Lewis. The first highways in the United States were developed in a very crude fashion. They followed lines of least resistance; the road surface was the natural soil; the grades were necessarily light, owing to the poor surface, and therefore the roads were circuitous. As the communities which these roads connected grew in population and importance, a better road surface was demanded, but little attention was given to the straightening of lines in order to furnish more direct routes. Little regard has been paid to the general appearance and attractiveness of highways between centers of population. In many cases the main connecting roads lead from some secondary or shabby street in one town or city to a street of the same class in another town; the impression which the user of the road gets of both towns is unfavorable, and the highway loses much in attractiveness and dignity. If such a connecting road approached and entered a town along well-designed roads and streets, increasing in importance and dignity until the civic center was reached, travel over them would be a pleasure as well as a mere attempt to get somewhere.

Every city and town has a straggling system of roads running out into the suburbs, which some day will become important streets, if not thoroughfares, but they are frequently allowed to remain straggling roads until the development of the abutting property has advanced so that a widening and straightening will involve an expense which is prohibitive. To advocate the improvement of such roads in anticipation of future growth requires courage, and will result in criticism from some quarters. To allow them to remain until necessity demands their improvement may be easy, but such a course cannot be justified.

Mr. Owen. JAMES OWEN, M. AM. SOC. C. E.—To appreciate the development of any of the systems of highways in the United States, the condition of the country must be considered. There are perhaps three or four methods of development: In the pioneer development, which took place during the Colonial era, when a man built a house distant from his neighbors, he built a road to it. He generally put his house on a hill. The road finally was extended into a main highway, and that is why a great many of the highways of the Eastern States are not properly located and are bad in grade and alignment; but they are fixtures. The developments along them preclude any main deviation from their original location. About 1820 the Government formulated the purpose of taking the Mississippi Valley and staking out the whole country in one section. The rule was to have a north and south road for each mile. The problems of direction and ease of access were ignored, and even the question of grade was not considered.

The great necessity of wagon travel to-day is through roads in every locality where there is a growing population. There is an utter lack of local appreciation of through highways.

AMOS SCHAEFFER, M. AM. SOC. C. E.—France has undoubtedly the best and most highly organized system of highways of any nation in the world. The systematic construction and maintenance of its public roads probably also dates back farther than that of any other country. The method by which the money is raised to construct and maintain the roads under the jurisdiction of the different authorities is indicated by their classification. Mr. Schaeffer.

Nearly every nation exercises more or less control over its highways, depending on their character and use. Where such control is exercised, the roads are usually divided into two or more classes which indicate whether they are main or secondary highways, and also largely under what governmental jurisdiction they are. This classification is very minutely carried out in France, and represents the relative importance of the roads as arteries of traffic. In most other countries there are not more than two or three classes. Germany is perhaps the most important exception to this method of control. It has no control over its highways, except in Alsace-Lorraine.

In the United States, during the past decade, a great many States have appropriated funds and created organizations for the improvement of the public highways. As these improvements are made, roads pass from local to State control, and the speaker predicts that the time is near at hand when the Federal Government will also take an active part in highway construction. It is even now exerting a great influence by encouraging the improvement of roads in various ways, recommending road materials, superintending the construction of experimental roads, and distributing literature on the subject throughout the country. When the Federal Government does take an active part in road construction, the "Design of Highway Systems" will be on broader lines than has yet been attempted.

In these remarks the speaker will confine himself to the location of roads rather than to the design of the cross-section of the roadway, drainage, road materials, methods of construction, and various other matters which form more particularly a part of the details of the design of highways.

The agitation for better roads has an international scope. The problem of co-ordinating and relocating existing roads, locating new ones to form national highways, and connecting them with those which will be built by other countries is one for the Federal Government to solve rather than the individual State.

The first considerations in the design of highway systems are line and grade, but these are influenced by a great many other circumstances. The most direct line between two large cities may be through a very hilly intervening country, and the best grades which could be obtained on a direct line might be prohibitive to heavy traffic. The

Mr. Schaeffer.

maximum gradient to be used, therefore, will have to be determined before the horizontal location. The adoption of a maximum gradient will possibly increase the distance between the objective points very materially, but distance must always be sacrificed to grade. If a main highway is to be constructed between large cities, some distance apart, there may be smaller intervening cities lying to the right or left of the most direct line which might be located on account of the established gradient. It might be more economical to locate such a highway through these intervening cities, even at the expense of distance, than to connect them with the main highway by branch roads. It might also be desirable to follow along the foot of a hill where protection from the sun in summer and from snow in winter would be afforded by trees and shrubbery, instead of going directly across a barren plain. Where draft animals are used, fresh water may be a consideration to be taken into account. It will be seen, therefore, that there are a great many considerations which exert an influence on the location of a main highway.

The influences which the speaker has outlined as affecting the location of a highway, except the question of grades, apply more particularly to new highways. The routes of existing highways are already determined, so that there is less choice of selection.

The State engineer is often confronted by other problems. It is usually his duty to transform a country earth road into a modern first-class highway. In this case, also, the established maximum gradient should not be exceeded, even at the expense of changing the alignment. The other considerations probably have already been complied with. It may be necessary sometimes to straighten out some bad curves or to widen the roadway at curves, or at intersections, to reduce the danger of collision between fast-moving vehicles. When this is done, a judicious treatment of existing conditions is necessary. For example, an old roadway may be well sheltered by trees which protect both the road and the users of it. It would be folly to cut down these trees for the purpose of widening the roadway at an intersection where it might be possible to construct a new additional roadway behind them. This would provide two roadways, one for each direction of traffic, which would be better than one wide roadway and would save the trees which would give protection to both roadways.

Wherever possible, trees and shrubbery should be saved at all points along a public highway. The esthetic surroundings along such a highway have considerable influence on various phases of life. They will do much toward keeping people in the country instead of having them move to the cities. They also have a tendency to distribute people from the cities in search of recreation instead of concentrating them in amusement and pleasure parks.

The width of a roadway is a question which requires careful consideration, and is governed more by the character of the traffic than by any other factor. A long-distance, through highway, on which the traffic is usually of the high-speed variety, requires less width of roadway than a short road between adjoining villages on which there is a mixed traffic. Two automobiles require less width and less distance to pass than two trucks. A road connecting two villages often accommodates such a variety of traffic as automobiles, trucks, carts, pleasure carriages, perambulators, pedestrians, and children running loose. Such a road must obviously be wider than one which accommodates a less dense and more rapid traffic. Mr. Schaeffer.

In addition to the kind of roads already described, there are those of less importance, which do not connect distant points, but connect smaller places with each other and with the main highways. In the United States these roads are destined to remain under the control of the local authorities for some time to come, and with but comparatively little improvement.

The design of highway systems applies to cities as well as to the country, and some of the requirements for a country highway apply also to city streets. Where it is proposed to lay out a system of streets for a new city, the problem is comparatively easy, but cities, as a rule, have not had their birth by design. The problem of the design of a street system is usually the planning of streets in territory adjoining a city already in existence, or the alteration of streets already built. Where the adjoining territory is undeveloped, the problem is also comparatively easy. Probably the most difficult problems in street design are the cases where a number of adjoining towns are annexed to a larger city. A good example of this is the annexation to New York City of the territory now known as the Boroughs of Brooklyn, The Bronx, Queens, and Richmond. Each of these territories comprised a large area of vacant land over which were scattered a number of small villages, the street system of each of which was oriented differently from that of the original city, and from one another. The solution of this problem is undoubtedly to develop into main arteries of traffic the old highways connecting the villages with the city and with one another by widening them sufficiently to accommodate the dense traffic which is sure to develop. As in country roads, it may also be necessary to straighten them, and this may be done with less regard for the surrounding topography than in the case of country roads, because their character will change as the city expands. The width of the roadway is also governed by the demands of traffic, but that of the street to which the city takes title should be governed in addition by the character of the development which will follow. In New York City, this development will probably be apartment houses, and therefore light, air, and access

Mr. Schaeffer. exert a more controlling influence than traffic. This is a factor which is often lost sight of, even at the present time. The result is that in the future, when expensive buildings occupy the streets, they will have to be widened at great expense.

The following summary, therefore, may be made:

The location and design of international and interstate highways should be undertaken by the Federal Government, that of other roads and streets by the State, county, town, or city, having jurisdiction over them.

The controlling influences on the location of highways are such grades as will be economical, both for traffic and construction, intervening cities and towns, topography, and vegetation.

For through city streets, the controlling influences are directions of route, sufficient width to accommodate traffic, and easy gradients; for streets of less importance, the location is governed by topography, and the frontage which will be provided for private development; the width is governed more by the requirements of light, air, and access, than by those of traffic.

Mr. Howard. J. W. HOWARD, ESQ.—The road problem of a nation or state is entirely different from that of a city. The highway problem has unconsciously been largely discussed from the standpoint of pleasure automobiles, but the important point must not be forgotten, namely, that roads are built to transport vegetable and mineral products.

The German highway system in the Kingdom of Prussia is excellent, and especially in the Province of Hanover where it is designed to obtain the maximum wealth of the soil and convey it by the shortest routes to the centers for further shipment by rail to the ultimate consumers in cities, and for export.

The radial system should be designed to reach out as far as possible from a city. Many fine highways may be built, but unless they are linked with little farms and country places, their real economic purpose will fail. Local roads are part of a system. They can be narrower, and can be constructed with less expensive surfaces than main arteries, but they must be just as viable as the main highways; otherwise, the products of the soil are blocked from coming to the great cities. This system of main roads and laterals likewise distributes the products of the central producing factories back to the people who have extracted and supplied the products of the earth: the true wealth producers of a nation.

Mr. Carter. C. E. CARTER, ASSOC. M. AM. SOC. C. E.—A comprehensive system is needed to connect all the towns throughout the State. The town should connect with the State system, thereby making a tentative system through its limits (considering only the town system, regardless of ownership). At present, a man who owns a small piece of

land divides it into house lots and locates the streets without consideration of the continuity of the highways. If the town system is already laid out, then development should be allowed only along these lines, unless any change suggested would better, or, at least, not be detrimental to, the town system as a whole. This can be accomplished by the town refusing to accept streets or allow municipal improvements to be placed in any street not shown in the system or subsequently approved by the proper authorities. Mr. Carter.

F. O. WHITNEY, M. AM. SOC. C. E.—Like most of the large cities of the United States, Boston is made up of several other cities and towns which have been annexed at different times, and each of these cities and towns contained several centers. In 1891 the State of Massachusetts passed an act requiring the City of Boston to appoint a Board of Survey, the duties of which should be to plan, immediately and as expeditiously as possible, a street system for the whole city, and such a Board was appointed. In 1895 its duties were transferred to the Board of Street Commissioners which has charge of the laying out of all streets in the city, and since that time it has constituted the Board of Survey in compliance with the original law. Mr. Whitney.

The law provided that these streets should be planned, and that their directions, widths, and grades should be determined, plotted, and indicated on maps. This work was done very thoroughly, the undeveloped portions of the outlying districts of the whole city being covered.

Particular attention was given to three classes of streets:

First, the connecting thoroughfares between the different centers of population and business. These were made as direct as possible by widening and straightening the old streets. The new widths were determined by considering the probable future traffic, and the grades were made as easy as possible in consideration of that traffic. Those streets were the arteries.

Second, the residential streets, which filled in the undeveloped spaces between the little villages. Their alignment was less direct. The grades were allowed to be steeper where necessary, and the widths, of course, much less than those of the thoroughfares.

Third, a class of roads which provided for pleasure travel, and was largely in connection with the parkways and the park system reservations of both the State and city parkways.

The law required that whenever public convenience demanded that streets should be constructed and laid out as public highways, the plotted lines and grades should be followed, and that private individuals, in the development of their property, should also conform to the lines thus laid down. The penalty imposed on individuals for not following these lines is that the city is prohibited from placing any public works in private streets which are not constructed on these lines and grades.

Mr. Whitney.

The topography of Boston is such, and the settlement of the territory has been so complete in centers, that it has been impossible to make the city over on any rectangular or other systematic development; but the irregular development has been considered by some as ideal from an esthetic standpoint.

Mr. Blanchard.

A. H. Blanchard, M. Am. Soc. C. E.—Highway systems may be considered from the standpoints of the Nation, State, county, township, city, town, and park. In this discussion the problem of design will be limited to a consideration of National, State, and county or township systems. City and town planning present many features peculiar to each, the consideration of which is not necessary in the design of the systems classified above. The design of highway systems includes consideration of the social, industrial, and agricultural development of a country; the inter-relationship between highways, railways, and waterways; the methods of transportation which will probably be used, such as horse-drawn vehicles, commercial motors, motor-busses, and light railways; and the limitations of grades on the different types of roads and pavements for each kind of traffic.

A national system for the United States would necessarily include trunk highways traversing the country from east to west and from north to south, and passing through the great centers of population, and through trunk highways forming connections between the important cities and these main highways.

State highway systems should be developed on the French plan, that is, main trunk highways constructed at the expense of the State, and county highways constructed by State aid under its supervision. Town highways may or may not be constructed with financial aid from the State, but they should receive the advantages accruing from such aid through the medium of its engineering department, as typified by the practice of the State of New York.

With the adoption of this plan of financing the construction of State, county and town highways, it becomes practicable to design a comprehensive system of State trunk highways connecting all important industrial, agricultural, and social centers.

The county system may be built up within the State system on the same principle, but from the local county standpoint. Under this plan, except in congested districts, town highways will generally be feeders to the State and county systems. It is obvious that the different classes are laid out by the unit of government directly affected. It is likewise apparent that if in a lower unit rests the responsibility covering improvement of highways of general interest to a higher political unit, vexatious and costly delays in the completion of the system of trunk highways will probably occur.

(4) EQUIPMENT FOR THE CONSTRUCTION OF BITUMINOUS SURFACES AND BITUMINOUS PAVEMENTS.

BY MESSRS. FRANCIS P. SMITH, H. B. DROWNE, JAMES L. GAYNOR, H. C. POORE, W. S. GODWIN, W. H. KERSHAW, W. H. FULWEILER, J. A. JOHNSTON, ARTHUR H. BLANCHARD, J. W. HOWARD, PHILIP P. SHARPLES, AND PREVOST HUBBARD.

FRANCIS P. SMITH, M. AM. SOC. C. E.—The earliest bituminous pavements laid in America were made with coal-tar, and the first mixing methods were very crude indeed, hand labor being used almost exclusively. By degrees, suitable machinery was devised, and, as the industry grew and sheet asphalt pavements were introduced and became popular, the development of paving plants was very rapid. In large cities, where the area of pavement to be laid was great, the plants were built as permanent fixtures. Where only a limited amount of work was to be done, the investment was too great, and the semi-portable plant was therefore developed. This was designed so that it could be taken down, shipped to some other place, and set up again, without too great expense. Next, the railway plant, built on flat cars, was devised. This was a great improvement, as it could be taken down or set up in a few hours, and was entirely self-contained. A very large number of plants of this type are now in use in the United States. Mr. Smith.

The permanent, semi-portable, and railway types are used chiefly in paving town and city streets, as hauling is expensive, and, in order to operate economically, the plants must be placed near the street or road to be paved. Where large and heavy machinery is involved, its economical transport, of course, is confined to railroads, which are an absolute necessity where such plants are concerned.

The comparatively recent and rapid development of the bituminous concrete type of construction for country highways has resulted in still another plant. Such highways are frequently, perhaps usually, too distant from railroads to make it possible to locate a mixing plant on the line of the railroad and economically haul the hot mixture from it to the work. Even if this could be done, the contracts, owing to local conditions, are frequently let to small contractors who are not able to purchase large mixing plants. Within the last few years, therefore, a number of plants have been designed which, for lack of a better term, will be described as of the concrete-mixer type. Their output is relatively small, and their use is chiefly confined to highway work. They are not as economical or as complete as the larger plants, but when properly operated, there is no doubt that they have their field of usefulness.

Mr. Smith. As the various types of plants have been described elsewhere, it has seemed more important to the speaker to discuss the principles involved in their design and operation than to attempt to describe them in detail.

Regardless of the type of plant used, three distinct operations are involved in the manufacture of bituminous pavements by the mixing method:

1.—Drying and heating the mineral aggregate,
2.—Preparing and heating the asphalt cement or bituminous cementing material,
3.—Mixing the hot mineral aggregate with the hot asphalt cement.

In a properly designed plant, the machinery for conducting each of these operations must be capable of handling sufficient material to insure the required output. This is a very important consideration, with reference not only to the time required to complete the work, but also to the quality of the mixture. Given ample mixing capacity, but insufficient drying and heating capacity, there will always be a strong temptation to rush the material through the dryer and mix it with the bituminous cement before it is dry enough and hot enough to insure the proper coating of the mineral aggregate. With the conditions reversed, the time of mixing each batch will be reduced in order to keep up with the output of the dryer, and this, of course, will result in a defective mixture in which the bituminous material is not evenly distributed throughout the mass and the various particles are not completely coated.

Where the drying and mixing are done in the same drum, as in the modified concrete-mixer type, the temptation first mentioned is always very strong. Furthermore, it is hard to obtain correctly the temperature of broken stone, under the best conditions, and in most plants of this kind it is difficult to get at the stone to test it, even if the machinery is stopped. Frequent stoppages, of course, will be strongly objected to by the contractor, and, besides, thermometers are frequently broken in this kind of work. Add to this the fact that these plants are usually run by men who are somewhat inexperienced (in fact, this is given by some manufacturers as one of the great arguments in favor of this type of plant), and it is not difficult to account for some of the unsatisfactory results obtained.

To understand more clearly just what is involved in the three operations mentioned, they will be considered separately.

Drying and Heating the Mineral Aggregate.—The mineral aggregate usually consists of sand, broken stone, gravel, or mixtures of these, and, depending on the kind of pavement to be laid, requires heating to a temperature between 250 and 350° Fahr.

Notwithstanding the fact that actual paving work is not usually carried on in rainy weather, it is frequently necessary to run very wet sand or stone through the dryer, owing to its exposure to the weather or because freshly dredged sand is being used. Unless ample drying capacity is provided, therefore, the output of the plant when using wet mineral aggregate will be greatly reduced. Many pavements are laid late in the fall or in early winter, and, under these conditions, much greater drying capacity will be required than in warm weather. Where the conditions vary as above described, or late in the season when the difference in temperature between early morning and noon is very great, any attempt at regulating the drying operation by allotting a fixed time for it, which is adhered to without change during the day's operations, is absurd and useless. The temperature of the mineral aggregate must be tested, preferably with a thermometer, at frequent intervals, and the heating period must be changed from time to time as found necessary, and regulated in accordance with the results obtained. Mr. Smith.

In an asphalt plant, over-heating has to be guarded against carefully and continually, yet the heating capacity of the concrete-mixer type of road plants is usually so limited that the tendency is to underheat rather than over-heat the mineral aggregate. Care should be taken, of course, to prevent over-heating in all cases.

When a mixture of sand and stone, or stone of different sizes is being used, care must also be taken that each batch of material is of relatively the same mesh composition. This requires great care in feeding the mineral aggregate to the dryer, and, unless this point is insisted on, the average contractor will totally neglect it, and the resulting pavement or roadway will be hopelessly lacking in uniformity. Generally speaking, a fine mixture requires a greater quantity of bitumen than a coarse one. With the same quantity of bituminous cement to each batch, marked variations in the mesh composition of the mineral aggregate will result in a pavement which is too rich in some spots and too lean in others. In the case of the bitulithic type of pavement, in which the grading of the mineral aggregate is probably carried to the highest point, uniformity of mesh composition is obtained by screening the heated stone into separate bins and recombining the different sizes in definite proportions by weight.

Preparing and Heating the Asphalt Cement or Bituminous Cementing Material.—In sheet-asphalt paving work, the refined asphalt is usually fluxed to the proper consistency with a heavy residuum oil or flux, although in some cases a ready prepared asphalt cement is used. In road work, a bituminous cement of the proper consistency and requiring no fluxing is almost always used. It should be melted in kettles, preferably of sufficient capacity for the day's run, and constructed so that they will not tend to over-heat or unduly harden

Mr. Smith. the material. The kettles should be fairly deep, rather than shallow, as this will minimize the hardening of the melted mass because of the relatively smaller surface exposed for the evaporation of the lighter oils. The best practice is to apply a slow fire until the material in the kettle is thoroughly melted, and then bring it up to the temperature desired, usually about 300° Fahr. Where the kettle capacity is small and it becomes necessary to re-charge it while in use, the tendency is to increase the heat unduly in order to melt the material rapidly to supply the demands of the mixing plant. This is especially true where a relatively hard and solid bitumen is being used. It must always be remembered that the bituminous materials harden when exposed to long-continued or high heat; and, when, for any reason, the material in a melting kettle is kept heated for an unusual length of time, sufficient flux should be added to restore it to its original consistency. This is well understood in the asphalt paving industry, where the consistency of each kettle of asphalt cement is determined by the penetration machine before it is used, and is brought to the proper point from time to time by the addition of flux.

The average road contractor pays no attention to these details, in fact, is usually ignorant concerning them, and the speaker often wonders that his work turns out as well as it does.

Mixing the Hot Mineral Aggregate with Hot Asphalt Cement.— In the sheet-asphalt paving industry, what is frequently termed a twin pug type of mixer is used. In this there are two parallel shafts, revolved by suitable gearing, and attached to them are blades which intermesh with each other and are at different angles on the shaft (somewhat in the same way that propeller blades are placed), so that they will throw the mixture from the ends and sides toward the middle. Some revolving-drum mixers of the concrete type are provided with blades to facilitate the mixing, and some are not. Some are heated from the outside and in others the products of combustion pass directly through them. The time required for mixing a batch depends on its size and the efficiency of the mixer. This must be determined for each plant, and, once determined, should be adhered to rigidly. In no case should the mixing process be commenced until the mineral aggregate and the bituminous cement are at the proper temperature. Assuming that the mixing period is comparatively short, it is unnecessary, and a distinct disadvantage under ordinary conditions, to have the mixing drum heated or the products of combustion pass through it during the process. The bituminous cement, when applied to the mineral aggregate, coats the particles with an extremely thin layer, therefore, at this stage of the operation, it is peculiarly susceptible to hardening by excess of heat. If the mineral aggregate and bituminous cement are heated to the proper temperature in the first place, the bituminous material will remain sufficiently liquid during the mixing process to

coat the stone properly. If either of them is too cold when they are brought together, they should have remained longer in the dryer or melting tank, and, for the reason above stated, no attempt should be made during the mixing process to bring them up to the temperature which they should have reached before they were mixed. Mr. Smith.

A paving mixture made with too hard an asphalt cement will be very difficult to rake or spread, and impossible to compress properly at the temperatures at which normal mixtures are ordinarily handled on the street. Raising the temperature of the mixture only tends to harden it still further. Mixtures containing too hard an asphalt cement will not give proper service, as they will crack in cold weather and grind out under traffic, and do not provide any margin of safety for offsetting the hardening action of time on all bituminous materials.

Of course, it is not necessary to state that the proportions in each batch should be weighed or measured accurately. In asphalt plants of the best type, each ingredient entering into each batch is weighed carefully. Where measuring is resorted to, this is done accurately by striking off the mineral aggregate carefully in special iron measuring boxes, and filling the asphalt bucket until the contents reach the level of a proper measuring gauge. Contrast this with the usual road contractor's method of operations and one will see a vast difference. In the speaker's opinion, it is not too much to say that uniformly good results will never be obtained until the methods used in constructing bituminous roads are closely patterned after those followed in the asphalt paving industry.

It may be interesting and instructive at this point to discuss somewhat in detail just what quantities of material pass through the three different processes previously mentioned for a given yardage of pavement. For this purpose, consider a sheet-asphalt plant having a capacity of 2 000 sq. yd. of 2-in. wearing surface per working day of 10 hours. The average weight of 1 sq. yd. of surface mixture 2 in. thick when compressed will be 200 lb. The total weight of the output, therefore, will be 2 000 $\times$ 200 = 400 000 lb. This mixture will consist approximately of:

Sand	79 per cent.
Dust or filler	10 " "
Bitumen	11 " "
	100 per cent.

The different portions of the plant, therefore, must be capable of handling the following quantities of material:

Dryer	316 000 lb.	= 126.4	cu. yd. of sand,
Melting tanks	44 000 "	= 22	tons of pure bitumen,
Mixer	400 000 "	= 200	tons of surface mixture.

Mr. Smith. The capacity of the mixer in a plant of the size under discussion is usually rated at 9 cu. ft. This means that the batch dumped into it contains 9 cu. ft. of sand plus the other ingredients. The average weight of dry, hot sand is about 95 lb. per cu. ft. In accordance with the formula previously given, and assuming that a pure asphalt cement is being used, each batch would consist of:

Sand	855 lb.
Filler	108 "
Asphalt cement	119 "
	1 082 lb.

It will take 370 batches of this size to turn out the required quantity of surface mixture. In a 10-hour working day, this means 37 batches per hour, or one batch every 1.62 min. Not less than one full minute, with a mixer speed of from 60 to 80 rev. per min., should be allowed for actually mixing each batch of sheet-asphalt surface mixture. This leaves a total of only 37 sec. in which to charge the mixer with the various ingredients and dump the finished mixture into the wagons. With a well-organized gang and a properly working plant of this type, only 20 sec. are necessary, but it can readily be seen that this is one of the features where seconds count. The mixer capacity of a plant is usually calculated very closely, and this makes it more than ever necessary that the capacity of the melting tank and dryer should be ample in order to furnish a full and uninterrupted supply of hot sand and asphalt cement, as it is almost impossible to make up for delays at the mixer.

Having determined the formula for any piece of work, and knowing the time required for mixing each batch, together with the size of the batch, one can calculate a similar schedule of operations for it, and ascertain just what kind and capacity of plant is suitable for the work. After determining these points, a contractor should never be permitted to mix and lay more pavement in a given time than is called for by the schedule. If he does, it is certain that some portion of the work has been slighted. This should be carried still further, if necessary, by determining the maximum number of batches permissible per hour and never permitting him to exceed this in an endeavor to make up by hasty work in an afternoon what he has lost in the morning on account of unfavorable conditions of any kind.

As stated previously, a standard sheet-asphalt pavement, 2 in. thick, when compressed, weighs about 200 lb. per sq. yd. Road surfaces of broken stone or mixtures of broken stone and sand, 2 in. thick, will vary from 175 to 250 lb. per sq. yd. The denser the mixture and the greater the proportion of large stone, the greater will be the weight per square yard.

After the mixture has been made, delivered to the road, and spread, it is necessary to roll it in order to compress it. Either of two types of rollers may be used for this purpose. The tandem type is generally used in laying sheet-asphalt pavements, and the road roller type (in which the wheels do not track) for highway work. Where the mineral aggregate is composed of small-sized particles and requires to be finished to a very smooth surface, as in city pavements, the tandem type of roller will produce better results and a more even surface. Where the particles of mineral aggregate are large, the type of roller generally used in road work is better for the purpose. It gives a greater kneading action to the large particles, and will effect better compression in such a surface than can be obtained with a tandem roller of the same weight per inch of width of tread. In addition to this, the total width of tread in a road roller is less than in a tandem roller of the same weight, and, therefore, gives a greater pressure per square inch. It is somewhat more difficult to finish the work smoothly with the road roller, but, for ordinary road or highway work, this is not as essential as for city streets. Mr. Smith.

Distributors.—The oiling of roadways results in the formation of a bituminous surface, and would therefore come under the present discussion. The chief piece of apparatus used in this kind of work is a distributing wagon for the oil or bituminous material. Where this oil is so heavy that it will not run freely at ordinary temperatures, it is necessary to provide means for heating it, either in the distributing wagon itself or in the tanks from which this wagon is filled. Such wagons are of two general types: gravity distributors, and pressure distributors.

The gravity distributors apply the oil to the road more or less uniformly and in a film of considerable thickness. This film, if of heavy oil, requires a long time to be absorbed by the roadbed, and, in order to make traffic on it at all agreeable, it is necessary to sprinkle gravel or sand over the surface of the oil as soon as it has been applied, otherwise it will be tracked into houses and spattered over vehicles and people riding in them. With a distributor of this type, the absorption of the oil by the roadbed is accomplished entirely by capillary action.

Pressure distributors are of two kinds. In one the oil is forced through small orifices in the distributing pipe by maintaining air pressure in the top of the tank from which the oil is being drawn. Thus the oil is forced downward to a slight extent into the roadway, but there is still a sticky and oily film on the surface much like that produced by the gravity distributor. A large part of the absorption of the oil by the roadway is accomplished by capillary action, and is more or less slow. Roads treated by this method, though less objectionable than when the gravity distributor is used, will still require the application of a coat of screenings or sand on the surface.

Mr. Smith. In the other type of distributor the oil is atomized by the action of the air pressure, in much the same way as in perfume atomizers and oil burners. When properly designed, distributors of this type will apply to the surface of the road, with considerable force, a mist of very minute oil particles which will be driven downward at a high velocity by the air pressure. In this way the oil will be driven to a considerable depth into the roadway, and the treatment may be regulated so that on the surface of the freshly oiled road there will not be any objectionable quantity of oil, thus obviating the necessity of applying a coat of screenings.

Mr. Drowne. H. B. DROWNE, ASSOC. M. AM. SOC. C. E.—During the summer of 1912, the speaker supervised some construction work on the Service Test Road in Philadelphia, on which a portable mixing plant of small type was used. This mixer is known commercially as the Rapid Heated Mixer.

Essentially, the machine consists of a four-wheeled truck, at one end of which is mounted a boiler and engine, and at the other a small cylindrical rotary mixer. Between the boiler and the mixer is a platform on which the loading is done. The mixing drum is surrounded with a hood, furnishing a heating space of about 3 in. between the shell of the latter and the mixer. The heat for this hood is furnished by a coal fire directly under the mixer. Additional heat is obtained from a kerosene torch which may be inserted within the mixing drum. A vertical blade running spirally around the inside of the drum serves to lift the material from the bottom and carry it to the top of the mixer, as the latter revolves. The material then falls to the bottom, and the same operation is repeated. The discharge spout is fixed in the center of the drum at the rear of the machine. The capacity of the mixer is 12 cu. ft., or a batch of about 1 300 lb., including the bituminous cement.

In this instance, a Topeka pavement was being constructed. The aggregate was composed of a mixture of sand and stone complying with the following specification:

Passing	200-mesh sieve,	5 to 11 per cent.
"	40- " "	18 to 30 " "
"	10- " "	25 to 55 " "
"	4- " "	15 to 22 " "
"	2- " "	not more than 10 per cent.

The various materials were taken from the stock piles in wheelbarrows to the loading platform and dumped into the mixer. The kerosene torch was then inserted within the drum, and, as the mixer revolved, the material cascaded through the flame of the torch and was heated to a temperature of about 212° Fahr. When this temperature was reached, the torch was withdrawn, and the asphalt cement,

which was heated to about 350° Fahr., was poured in. A cover was then placed over the opening in the loading end of the mixer. The batch was allowed to mix with the asphalt for from 1 to 2 min., at the end of which time a perfect mix was secured having a temperature of 250° Fahr. Mr. Drowne.

The output of the machine varied, depending on the dryness of the mineral aggregate. On an average, from four to five batches were mixed per hour. When the materials were warmed before being put in the mixer, six batches per hour were mixed for 1 or 2 hours, or as long as the warm material lasted. One batch of material would lay about 5 sq. yd. of pavement, 2 in. thick when rolled. The pavement was constructed on a macadam foundation, and there was some loss, due to the material being compressed into the voids of the surface. If laid on a concrete foundation, one batch would probably have made a somewhat greater yardage. The manufacturers of this machine claim an output of 250 sq. yd. per 10-hour day per machine. It is generally recommended that these machines be used in pairs. It takes from 6 to 12 min. to bring the material up to the proper temperature before adding the asphalt cement. If only one machine is used, and four or five batches per hour are mixed, the time required for each batch is from 12 to 15 min., therefore, considerable time is wasted by the men working around the machine. If the machines are used in pairs, the men can be kept busy practically all the time, and it is the only economical way to use machines of this type. The output of two of them in a 9-hour day would be about 360 sq. yd. In a bituminous concrete in which the aggregate does not form so dense a mixture as the Topeka, but is composed of larger stone particles, the output of the machine is considerably increased.

If the cost of labor is $2 per day, seven laborers being required, and an engineer at $3.50 per day, the labor cost of the operation would be about 4.8 cents per sq. yd., on a basis of 360 sq. yd. per day. The cost of coal, kerosene for the torch, depreciation of the machine, and supervision, would add probably about 4.5 cents, making a total cost of 9.3 cents per sq. yd. It is essential that the stock piles, and the kettle in which the bituminous material is heated, be near the mixing plant, in order to accomplish economical work.

The importance of drying the material must not be lost sight of in using machines of this type, and this part of the operation takes up the greater part of the time. Some means of heating and drying the materials must be used before putting them into the mixer. On the Philadelphia work wood fires were built in pipes placed under the stock piles. This preliminary heating helped considerably, but if the materials were not covered with tarpaulins at night a slight rain would dampen them to such an extent that the mixing would be seriously delayed. With mixers of this type there is not the slightest danger

Mr. Drowne. of overheating the materials, provided the batches are discharged when they reach the proper temperature; but if they are left in the mixer too long they will become overheated.

This machine is also adaptable for mixing cement concrete. When used for this purpose, a swinging trough is fixed under the discharge spout. The mixed concrete falls from the spout into the trough, which has such a pitch that the concrete runs down to the end and falls on the road. As the trough is 10 ft. long and may be swung through an arc of 180°, a width of about 20 ft. of surface can be covered with concrete at one passage of the machine, without wheeling any of the concrete.

The speaker thinks a plant of this type is a good one for small jobs, or for repair work, where small plant cost is desired. These machines cost about $1 200 each.

Mr. Gaynor. JAMES L. GAYNOR, ESQ.—A rapid mixer was used during October and November for mixing 1½-in. stone with an asphalt cement. On an average, 350 yd. per day were mixed. Instead of using 12 cu. ft. to the batch, about 15 cu. ft. were used, the mixer being loaded full. The stone was bone dry. With a battery of two machines, a capacity of 700 cu. yd. per day should be secured. The labor charge for one machine was about 9 cents per cu. yd.

Mr. Poore. H. C. POORE, JUN. AM. SOC. C. E.—During the season of 1912, the speaker was connected with the construction of about 55 miles of bituminous concrete pavement. This work was done by one of the New England States, which, having had the usual experimental sections under test for the past 4 years, decided to use a cold-mixed bituminous concrete for both resurfacing and new work.

Refined coal-tar was used as a binder, this material being shipped in tank cars to the nearest railway station, where it was steam-heated and barreled by the contractor.

During the height of the season, eighteen mechanical mixers were in operation, laying daily a total of 3 000 ft. of 14-ft. road surface, 2 in. thick.

The type of mixer generally used was one manufactured by the Municipal Engineering and Contracting Company. It is similar to the ½-yd. cube batch cement concrete mixer, and has an oil torch heating device for use when bituminous concrete is mixed. The machine is mounted on four wheels for transportation. It consists of a revolving iron box, mounted on its diagonal axis, and driven with direct gearing by the steam engine mounted on the same frame. The mixed material is discharged by tipping the cube, and the mixing chamber is loaded with a sliding skip operated by a small cable hoist.

An air compressor for supplying the oil torch is belted to the engine. Common fuel oil under air pressure forms a blast in the center of the mixing chamber sufficient to dry the mineral aggregate and expedite the

work during cold weather. As the specification called for a cold mix, the blast was not necessary throughout the day's work. Mr. Poore.

The plants were operated in two ways: either as a portable plant moving along the road each day, or as a stationary unit at the stone crusher.

The first method was followed where the work consisted of scarifying the old macadam and adding a new 2-in. bituminous concrete surface. Set-ups were made at the intervals covered in a day, usually about 200 ft. A 12 by 12-ft. dumping board was used under the loading skip, on which to dump the broken stone hauled from the railroad siding or stone crusher. The mixer was placed on planks in the center of the road, being hauled ahead by the steam roller at the end of the day.

Two 15-gal. portable kettles provided sufficient hot bituminous material. The proper quantity for a batch was measured out by hand and carried in buckets from the side of the road to the loading chute. Six iron barrows, well oiled to prevent the coated stone from sticking, were used in carrying the hot mixture to the road, where it was raked out to the required depth.

One roller was able to prepare the old macadam and roll the mixture delivered each day. When the mixer was used as a permanent unit at the stone-crushing plant, the mixer platform was built at the same elevation as the bottom of the stone bins, and from the latter the stone could be discharged directly to the loading skip. To allow the uncoated stone for the foundation course to fall by gravity into wagons, it was necessary to leave an intervening space of 7 or 8 ft. between the stone bins and the mixer platform. In some cases, however, the mixer was placed on the other side of the bins, and then an extra chute was built to feed into the loading skip.

Many of the mixers ran three ½-cu. yd. batches in from 10 to 15 min. A 1½-cu. yd. bottom-dump wagon was placed to receive these three batches, and then hauled to the road, a 2-mile haul often being economical. There was no chilling of the mixture. A larger kettle was used at the stationary plants than on the resurfacing work. The buckets of hot bituminous material were handed from the ground by the kettleman to the man on the raised mixer platform, and he emptied them into the mixer chute.

One engineer, one helper, one loading man, and one kettleman were required for the mixer when in operation. The broken stone was not touched by hand until raked out on the road.

The cost of the plant was:

Mixer complete....................	$1 550
Two kettles........................	200
Small tools and lumber............	100
	$1 850

Mr. Poore. Practically 600 sq. yd. were turned out per day per plant. On country roads, where a cold-mix bituminous concrete is specified, such an equipment may be considered very satisfactory.

Mr. Godwin. W. S. GODWIN, ESQ.—The cardinal point in bituminous paving is unquestionably uniformity. This applies to all the different methods of construction, surfacing, penetration, and mixing.

Irrespective of the method, cost, or kind of equipment, there are fundamental requirements which must not be ignored, if lasting qualities in the paving are expected. These can only be obtained by the proper use of appliances designed and built by those who are thoroughly familiar with the materials and the methods of construction.

In view of the fact that the cost of the product of the equipment is in inverse ratio to the volume of the output, economical production can only be obtained by having an output so large that the overhead cost does not assume undue proportion.

Cold Surface Treatment.—Bituminous materials can be properly and economically applied cold from a tank wagon drawn by motor or horse. It should have, across the rear, a distributor adjustable in width from 6 to 12 ft., thus avoiding the application of narrow strips. The distributor proper should have small openings or spraying nozzles at short intervals for the entire length, arranged so that they will entirely cover the desired width of roadway, and not apply the material in strips.

Unquestionably, the most difficult factor to control is the uniform distribution of the necessary quantity of bituminous material per square yard. This can be accomplished by keeping a uniform air or steam pressure in the tank, or by a pump connected between the tank and the distributor proper. Unsatisfactory results are obtained with either of these methods if the speed of the wagon or the motor varies. This objection, however, can be overcome by using a specially designed pump connected with the running gear of the wagon or truck, or by drawing the tank wagon by a steam roller at a uniform speed. Any of these distributors should be capable of distributing evenly from ½ to 1½ gal. per sq. yd.

Gravity distributors of any kind have the disadvantage of being able to handle only the light gravity oil; the quantity distributed also gradually decreases as the tank empties.

Hot Surfacing and Penetration Methods.—If the pressure distributors are equipped with interior steam coils, and sufficient steam is supplied to keep the bituminous material at a uniform temperature of about 280° Fahr., they are capable of distributing the heavier grades for either the hot surfacing or the penetration methods of construction.

The equipment generally used in the penetration method has been portable or semi-portable melting kettles, having capacities ranging

from 50 to 500 gal. and hand-distributing pots. This method of heating and applying is expensive and the results obtained are invariably crude. The bituminous material is often too cold, and, in some cases, is overheated and damaged. It is quite apparent that when a pouring pot is used, the uniform distribution of the hot material depends entirely on the workmen. Even with the utmost care, non-uniformity shows on the finished roadway. An excess of bituminous material will collect in spots and hold any kind of stone or dirt, even after the completion of the roadway. This causes an uneven surface which is very objectionable. Mr. Godwin.

The arrangement and equipment for penetration work is most satisfactory when the contractor receives the bituminous material at the nearest railroad siding, in 6 000, 8 000, or 12 000-gal. tank cars, equipped with interior steam coils. A 20-h.p. boiler may be attached to the steam coils in the tank car and thus heat the material to the desired temperature. If this arrangement is provided at the railroad siding, the hot material may be run by gravity into the distributing wagons. If this is not practicable, the material may be pumped from the car to the wagons. A horse-drawn distributing wagon may be hauled from the railroad to the work and then may be attached to a steam roller.

Bituminous material received in barrels costs the contractor an additional sum of at least 2 cents per gal. for each barrel and also the freight on the barrels, which is about 15% of the gross weight. Besides, he has two or more melting kettles to operate and a very large bill for fuel, to heat them.

A 20-h.p. boiler and a 600-gal. distributing wagon will cost about $1 000, and, with an average haul from the railroad siding, should cover 800 sq. yd. per hour. Two 400-gal. melting kettles, at $400 each, and a dozen buckets and pouring pots will cost about $850, and will not cover one-half as great a yardage. It is a case of inferior construction at an exorbitant cost, if the proper equipment is not used.

Should the extent of the work not warrant the purchase of such a plant, there should be secured a strong, well-built 500-gal. melting wagon and a hand distributor, having a capacity of at least 30 gal., mounted on wheels, and having a regulating distributor at least 20 in. wide. A distributor of this kind costs $65, and should pour 250 sq. yd. per hour, using 1½ gal. in the initial pouring and ½ gal. in the flush coat. The use of pouring pots should be avoided if possible.

Mixing Methods.—In the manufacture of bituminous mixtures of any kind, uniformity is the principal factor. This applies, not only to proper proportions of each different ingredient used, but to the temperatures at which they are heated and mixed.

The mineral aggregate, composed of stone, sand, and inorganic dust, must be heated uniformly to the proper temperature, and in

Mr. Godwin.

such a way as to prevent segregation of the larger from the smaller particles. This is a serious matter when different proportions of two or more sizes are used. The aggregates are usually heated in a cylinder dryer, with external heat. The heat is then drawn through the interior, the different sizes, in the proper proportions, being fed continually through the hot cylinder. If a batch heater and mixer is used, the proper proportions are measured or weighed before being placed in the mixer.

The kettles must have sufficient capacity to provide the quantity of bituminous material required to coat the mineral aggregate as it is heated by the dryer. The heat should be uniform and not so great that it will "burn," or harden any portion of the material. The melted material should be agitated slowly by compressed air. This is especially necessary where two kinds are used to obtain the proper consistency. The melting kettles should be protected from the rain, as water not only damages the bituminous material, but causes it to foam and run over the sides of the kettle, in some cases causing serious fires.

The quantity of hot material for each mix or batch should be measured or weighed accurately, and not mixed with the mineral aggregate until the stone or sand is of the proper temperature.

The hot mineral aggregate and the hot bituminous material should be mixed quickly and uniformly, with as little loss of heat as possible. The resulting homogeneous mixture should be spread quickly and evenly with strong iron-shank rakes and thoroughly rolled on a solid foundation.

If a portable batch mixer, having an interior flame in the drum, is used to mix the heated mineral aggregate with the bituminous material, the heat must be cut off before the latter is placed in the mixer, otherwise the excessive heat will damage it. Any method of mixing which allows the bituminous mixtures to come in contact with the flame or a heat in excess of 500° Fahr., if only for a short time, will convert the bituminous material from an adhesive and malleable consistency to a hard and brittle one, entirely unsuited for paving.

To receive their ultimate compression, mixtures similar to bituminous macadam and bituminous concrete, having a large percentage of stone, should have their final rolling with a 3-wheel roller weighing at least 10 tons. If a 5-ton tandem roller is used for the initial rolling, a more uniform surface will be obtained on the finished paving. The same method of rolling should be used for sheet asphalt, but both the rollers should be of the tandem type and weigh 2½ and 7 tons, respectively.

These fundamental principles must be adhered to, in order to obtain uniform and lasting paving, irrespective of the method and equipment used.

Mr. Godwin.

The cost of heating and mixing plants depends principally on their capacity and the care and material used in their construction. A small portable batch heater and mixer, similar to a concrete mixer, and capable of heating and mixing about 7½ tons per hour to a temperature of 300° Fahr., costs $1 500. Mixers of this class are only capable of mixing stone which is larger than ¼ in. As the bituminous material is placed in these mixers hot, a 500-gal. melting kettle is required.

For close or dense mixtures, stationary, semi-portable, and railroad plants are used.

Semi-portable plants, comprising the heating drum, mixer, melting tank, etc., cost $7 500, exclusive of any building, and have a capacity of about 75 sq. yd., or 7½ tons, of sheet-asphalt mixture per hour.

The improved railroad plants, which cost about $12 000, are capable of heating and mixing sufficient asphalt and sand to a temperature of 325° Fahr., to lay 175 sq. yd., or 17½ tons, of sheet asphalt mixture per hour.

The modern duplex stationary plant, in which the large dryers, 15-cu. ft. mixers, conveyors, etc., are operated with independent motors, cost about $33 000, including a steel building. These plants have a capacity of 500 sq. yd., or 50 tons, of sheet-asphalt mixture per hour.

As mixtures of stone are laid at a lower temperature and require less bituminous material than sheet asphalt, the capacity of plants increases about 18% when heating and mixing for paving of this class.

In buying a bituminous mixing plant of any kind, the contractor or municipality should receive bids only from companies which have had considerable experience in the manufacture of such machinery. It should be required that the plant be erected and operated under the direct supervision of the builder until it has met the guaranteed requirements. The guaranty should be for a certain number of pounds of properly heated paving mixture at a specified temperature, per day of 10 hours, and not a certain number of square yards. As all dense bituminous mixtures, when compressed to 2 in., weigh very nearly 200 lb. per sq. yd., this portion of the guaranty can easily be changed from square yards to something which is definite and easily ascertained. The contract should also state the maximum quantity of fuel to be consumed in 24 hours, and last, but not least, the date when the finished plant will be completed, erected, tested, and ready to run to the guaranteed capacity.

Mr. Kershaw.

W. H. Kershaw, Assoc. M. Am. Soc. C. E.—There is one class of equipment which has not been given proper consideration, and that is storage plants for road oil.

Equipment is acquired or improved because of the increased efficiency or saving in cost accomplished by its use. If it was thoroughly understood that equipment for the temporary storage of road oils,

Mr. Kershaw. tars, and asphalts would earn a satisfactory return on the investment, interest in this branch of road work would be increased.

It has been the custom in the past, when buying light oil, heavy binding oil, tar, or asphalt, to order one or more tank-cars, and then hold the cars until the material has been used. With the exception of one or two companies, no charge per day for demurrage on cars has been made for the use of this equipment. A charge of $1 per day is collected by the railroads in all cases, but, of course, none of this goes to the owner of the cars. The economic loss resulting from holding tank-cars out of service has been considered to fall on the shipper, but in the final analysis it is apparent that the price of the oil must cover the loss. Just what this loss of service for a single tank-car amounts to can be better understood when the following figures are considered.

At present, the leasing value of a tank-car is about $1.25 per day; that is, the seller either pays that amount in the form of a lease or, if he owns the equipment, can, in turn, lease it to some one else for that figure. This $1.25 per day practically covers the maintenance and depreciation of the car, and does not include an earning on the equipment which its owner is justified in expecting. A study of Table 1, which gives the time consumed in delivering a full carload (8 000 gal.), by the same car, to cities with and without equipment, shows the injustice of allowing the same tank-car charge to apply for all deliveries.

Table 1 gives an actual record of several cars which were in the road-oil service in the East during 1912, but for convenience the cost figures are based on a leasing value of $1 per day. In considering this record, it must be borne in mind that the producer or seller is carrying his tank-car equipment for 12 months in the year, and during the road season (from 6 to 8 months), is using the cars to the limit of their capacity. For the remainder of the year he has nothing for them to do or is turning them into some branch of the service which does not bring him an adequate return for their use.

From this table it will be noted also that a car can be shipped to a town or a city having equipment, and make a round trip in from 9 to 15 days, at an actual cost of from $12 to $25, delivering in that time a full load of 8 000 gal. When the tank-car charge on business of this class is added to the base price, it makes possible a lower quotation than can be given on deliveries made to points without equipment, where the car is gone from 20 to 100 days, in delivering the same quantity of oil. The shippers are ready to make lower quotations to cities equipped with storage plants, than can be made to points where their cars are delayed.

The fact that the installation of this equipment results in a material saving has been recognized by several of the large users of road oil, as witnessed by the following examples.

District of Columbia.—The District of Columbia has erected six 12 000-gal. and one 15 000-gal. road-oil tanks, these tanks being situated at various points throughout the District convenient for distribution. Three of the tanks are at the Property Yard of the District of Columbia, at 12th and N Streets, Northeast, on a siding of the Baltimore and Ohio Railroad. Fig. 1 shows only the 15 000-gal. tank of this particular group. There are two 12 000-gal. tanks directly under the railroad trestle. All these tanks are fitted with steam coils. Between the two 12 000-gal. tanks, and extending out under the end of the railroad ties, there is a mixing box, containing a mixing pug, and there are both water and oil inlet pipes, for the manufacture of emulsified road oil. Mr. Kershaw.

TABLE 1.—RECORD OF TANK-CARS.

*Car made trip with material other than road oil.
†For repairs.

There is a single 12 000-gal. tank at each of the following outlying points: Chevy Chase, Md., Deanwood, Uniontown, and Tacoma Park,

Mr. Kershaw. D. C. Fig. 2, the 12 000-gal. tank at Tacoma Park, shows the type of equipment in the several suburban districts mentioned. All the tanks have heating coils, and the average cost of the 12 000-gal. tanks in place, complete, including coils and erection charges, was $600.

Springfield, Mass.—The storage equipment at Springfield, Mass. (Fig. 3), consists of two 10 000-gal. tanks, carried on concrete footings. These tanks are arranged so that there is a fall of 2 ft. from the bottom of the tank-car, as it stands on the trestle, to the top of the receiving tank, and a fall of 2 ft. from the bottom of the receiving tank to the top of the distributing wagon. Each tank cost $344, f. o. b. Springfield, Mass., and the cost of installation, including piping, was $812, making the total cost $1 500. These are single-compartment tanks, and have no heating coils.

Borough of The Bronx, New York City.—This Borough bought four 6 000-gal. tanks, formerly used as railroad tank-cars, and assembled them on wooden trestles, arranging the piping so that the oil could be run into any tank desired. This was accomplished by placing a continuous main oil line with a shut-off valve on each tank connection. Figs. 4 and 5 show the arrangement of the tanks and piping.

These four tanks cost $950, f. o. b. New York. The construction of the wood trestles and the concrete foundations carrying them, together with the erection of the tanks and the complete piping, cost $750. The cost of painting the tanks and pipes was $70, making the total cost $1 700 for the complete equipment. The difference in elevation between the railroad track and the bottom of the pit makes it possible to fill the storage tanks and, in turn, load the tank-wagons from storage by gravity. These tanks are at 202d Street and Webster Avenue, on a siding of the New York Central Railroad.

Greenwich, Conn.—The Town of Greenwich, Conn., has a two-compartment tank of 12 000-gal. capacity, one compartment being fitted with steam coils. Fig. 6 shows the arrangements of the tank, which is in the side of a railroad fill, thus allowing enough fall to transfer the oil from the tank-car to the storage tank, and from storage to the distributor, by gravity. The cost of this installation was rather high, owing to the number of concrete abutments required to carry the pipe line from the tank-car to the tank and from the tank to the driveway. The cost was as follows:

Tank, f. o. b. shipping point	$327.96
Freight	52.00
Piping	165.00
Concrete abutments	230.00
Painting	15.00
Extras	5.00
Total	$794.96

Amies Road Company.—The Amies Road Company has erected seven 12 000-gal. tanks of the type recommended, at Glen Mills and Rock Hill, Pa., Bound Brook, Millington, Great Notch, Springfield, and Lambertsville, N. J. Fig. 7 shows the tank at Bound Brook, N. J. Mr. Kershaw

Recommended Type of Plant.—The capacity of tank-cars in the road-oil service varies from 4 000 to 12 000 gal., hence a tank 8 ft. in diameter and 30 ft. long, with an approximate capacity of 12 000 gal. is recommended.

RECOMMENDED TYPE OF STORAGE PLANT

FIG. 9.

Fig. 8 shows steel supports for the tank, which are recommended as less expensive than concrete and equally efficient. Fig. 9 shows the piping arranged so that it can be put into the tank through the dome after erection, and then connected up with a series of unions. In every case the tanks should be equipped with steam coils, thus making it possible to handle any of the heavier grades of binding oils, tars, or asphalts, as well as light road oils. The cost of these coils

Mr. Kershaw. is nominal, and as these plants are usually constructed in the city yard, where a steam plant is in operation or where a steam roller can be quickly connected, it is a profitable investment to put in the coils when the tanks are erected, even though the possibility of using them for anything but light oil cannot be foreseen. Experience has proven the merit of the following suggestions:

1. The tank should be placed so as to give a minimum fall of 2 in. in 30 ft. toward the outlet end.

2. The outlet should be placed as near as possible to one end of the tank.

3. It is important that the arrangement of steam coils in the tank should be such that a coil is placed immediately above or around the opening in the outlet pipe, thus preventing any possibility of the outlet becoming blocked by the collection of cold, solid material.

4. The steam coils should be placed on a cradle as low as possible in the tank. A maximum distance of $\frac{3}{4}$ in. between the bottom of the steam coil and the bottom of the tank is recommended.

5. When there is a possibility of using the storage tank for the handling of heavy materials late in the year, it is recommended that the outside piping be steam-jacketed.

A number of advantages accrue from the erection of storage tanks, such as the removing of all incentive to apply oil when the climatic conditions or the condition of the road surface are not favorable, and the possibility of altering the character of the oil to suit special conditions. The main reason, however, for investing in equipment of this kind is the fact that it is highly profitable and will earn a large return on the investment.

The city equipped with storage tanks immediately becomes one of the most desirable customers, and can obtain lower prices than cities not thus equipped. In the past it has not been unusual for towns using from 100 000 to 200 000 gal. of oil to pay the railroad company more than $1 000 per year in the form of demurrage, and quotations have been made in favor of the towns equipped with storage, which net a saving of from 2 to 5 mills per gal.

Mr. Fulweiler. W. H. Fulweiler, Assoc. M. Am. Soc. C. E.—The speaker wishes to present a few notes on the practical operation of some motor sprinkling trucks during 1912. These trucks were used in applying bituminous material in what might be termed a surface penetration treatment. In other words, the endeavor was to get the material to penetrate the upper 1 in. or $1\frac{1}{2}$ in. of the macadam surface, rather than to build a blanket on top of it.

In order to secure this penetration, it is essential that the surface of the road be cleaned very carefully and the larger stones composing the wearing course exposed. Even with the most careful sweeping,

it was difficult to secure a surface sufficiently free from dust to allow the uniform application of the bituminous material from gravity wagons, the material being apparently repelled by the microscopic layer of dust on the stone surface. It was evident, therefore, that some form of distributor was required from which the material would be forced under sufficient pressure directly into contact with the stone, so that the dust covering would be brushed to one side. Mr. Fulweiler.

A machine of English type, manufactured by Tar Roads, Limited, London, was purchased. It was provided with a pump geared to the wheels, and by means of the reducing valve enabled a sufficient pressure to be kept on the spray lines, so that with a little care in driving the horses, quite successful results were obtained, but the weight and the small capacity of the tank precluded the use of such an apparatus where there were long hauls from the tank-cars.

With a haul of not more than 1 mile, the horse-drawn type of machine seems to work quite economically, but for a haul of more than 2½ miles, and running up to 15 or 18 miles, it is entirely out of the question.

Two 5-ton chassis, provided with 900-gal. tanks, were equipped with rotary pumps geared to the transmission, through a dog clutch, so that they could be operated when the truck was in motion or at rest. By including a pressure-reducing valve and using a speedometer, it was possible to secure a very uniform rate of distribution.

The quantity of material delivered per square yard depends on the pressure and viscosity of the material, and this, in turn, on the temperature, so that by increasing the pressure or running the truck more slowly in the morning, or during cold weather, it is possible for the driver, after a little practice, to gauge very accurately the quantity he is delivering. The pressure can be varied from 20 to 200 lb. per sq. in., and take care of any ordinary change in the viscosity, due to temperature.

The great difficulty experienced in distributing the material uniformly is mainly in hilly countries. The ordinary motor truck has not enough power to climb the various grades at the same speed, so that it is necessary to change the gear frequently, or climb a hill on a very low gear, which results in considerable loss of time. This requires the driver to do some rapid changing of the relief valves which control the pressure, and considerable experience is necessary to adjust the pressure and speed accurately and economically. It appears that not less than 80 h.p. would be required to climb average hills in the East.

Apparently, the larger the truck (and, therefore, the load), the more efficient it is, but, when operating in country districts, this is limited by the fact that the average township bridge will not carry more than 10 tons. For operation only in the city, or in districts where there is

Mr. Fulweiler.

improved bridge construction, there seems to be no reason why a $6\frac{1}{2}$- or 8-ton truck might not be practicable, but 5 tons seems to be all that can be used in the country.

Another difficulty is due to the wheel base of the truck. On many country roads the shoulders will not bear the concentrated load on the rear wheels, so that it is frequently necessary to run long distances before reaching a suitable point to turn the truck. From 12 to 13 ft. seems to be the wheel base handled most economically on average roads.

In operating trucks to the maximum capacity, the greatest difficulty is due to the fact that the road is not always covered as it should be with a light coating of sand chips or gravel after the application of the material, in order to prevent it from picking up under traffic. In working from one point to another, throughout the country districts, especially about harvest time, it seems to be impossible, or at least very difficult, to secure sufficient labor to apply the covering as fast as the machine will apply the material. In a great majority of cases, the limiting factor for the truck in a day's work is the ability of the laborers to cover the material.

The use of mechanical sand distributors would probably be economical where the haul is short, but where it is from 3 to 4 miles long, it would seem that they are quite out of the question, and that the most economical method is to have the covering material spaced properly along the roadside in piles, about 60 ft. apart, and then hire a gang of from 10 to 12 men and carry them from place to place with the truck to do the spreading. In this way from 2 to 3 miles of 14-ft. road can be treated daily, applying $\frac{1}{3}$ gal. of binder, and from 12 to 18 lb. of covering per sq. yd.

Mr. Johnston.

J. A. JOHNSTON, M. AM. SOC. C. E.—The first pressure-distributing machine brought into Massachusetts by the Highway Commission was not, as has been stated, one in which air pressure was pumped in over the tar, thereby forcing out the tar and oil. The air pressure was not pumped directly into the tank-wagon. The bituminous material was pumped out of the tank, and there was an air chamber attached to the pump to regulate the flow. The Aitken machine (the one referred to) gave fairly good results, but was cumbersome. It held from 1 000 to 1 200 gal., weighed 10 tons when loaded, and was mounted on rather small wheels. Much difficulty was experienced in getting it over unimproved roads in going to and from the State roads, and on many such roads it cut into the soil so deeply that two steam rollers were required to pull it through the bad places.

To overcome these difficulties the speaker devised an apparatus consisting of a steam pump mounted on a separate carriage and fastened behind an ordinary tank-wagon; it was quickly detached from an empty wagon, and re-attached to a full one. The bituminous material was

pumped from the tank-wagon and forced into the road at a pressure of not less than 70 lb. per sq. in. The working principle of the machine is a duplex steam pump with a liberal air chamber; and, to insure practically constant pressure, a release valve is set so that when the pressure exceeds 90 lb., the excess material is forced through a by-pass back into the suction. The quantity of material applied per given area is regulated principally by the rate the wagon travels over the road. There is no speedometer, but the foreman, by the aid of his watch and by counting the revolutions of the wheels, determines how fast the machine should travel. That method seems to be crude, but it has given very good results. It is difficult to calibrate such a machine, because so many factors enter the problem, namely, temperature, viscosity, and kind of material, and such items vary so widely that no set rules can be made, and much must be left to the man on the job. Mr. Johnston.

The method of doing the work is as follows: The bituminous material is shipped to the most available railroad siding in tank-cars. If the material is so heavy that it requires heating before it can be used, the tank-cars are equipped with steam coils, and a portable steam boiler is set up and connected to them for heating. If the bituminous material is tar or oil of about 90% so-called "asphaltic content," the material can be pumped from the top of the tank in about 18 hours after steam has been turned on. A steam pump attached to the boiler is used for this work, and is piped so that the bituminous material is pumped from the top of and returned to the bottom of the car, thus circulating it and overcoming any tendency to stratification. When the bituminous material has attained the proper temperature, it is pumped into tank-wagons holding about 700 gal., which are also equipped with steam coils for re-heating if necessary, and hauled with horses or traction engine to the work. These wagons, which weigh when empty about 3 000 lb., can, when loaded, be easily pulled by a single pair of horses on any ordinary road. The wagons are often jolted over rough surfaces of roads under construction, hence it has been found difficult to keep tight joints in the ordinary steam coil. This trouble has been obviated by using a special form of coil, constructed so that there are no joints within the tank. The coils are fastened securely, and no leaks can occur.

When the wagon arrives at its destination, the horses are unhitched, the wagon is coupled to the steam roller, the sprayer is then attached behind the wagon, steam connections are made to the roller, which then pulls the combination over the road and furnishes steam to drive the pump on the sprayer. The contents of the wagon can be applied on the road in an absolutely uniform coating in 20 min. When the wagon is empty, it is replaced by a full one, and the process continues while the empty tank is returned for refilling. Several tank-wagons

Mr. Johnston. are used, and, with such an equipment, 1 mile of road per day has been treated with a coating of ½ gal. per sq. yd., and covered with pea stone or gravel. Much more could be done if the grit covering could be handled to better advantage. Heating, hauling (3 miles), and applying the bituminous material by this method has been done at a cost of 1¼ cents per gal.

Motor wagons are economical for long hauls from central plants, but, up to a haul of 3 or 4 miles, they cost more to operate than the horse-drawn tank-wagon.

Mr. Blanchard. ARTHUR H. BLANCHARD, M. AM. SOC. C. E.—The selection of plant equipment for the construction and maintenance of bituminous surfaces and bituminous pavements, which will be economically suitable in methods and materials for local requirements in each case, is the key-note of successful work in this field of highway engineering.

A review of the various mixing machines, mechanical distributors, and plant accessories, and a consideration of the many kinds of mineral aggregates and types and grades of bituminous materials used in the construction of bituminous concrete and bituminous macadam pavements, demonstrate that the construction engineer and contractor should have a thorough knowledge of the limitations of each type of machine on the market. To a lesser degree, the same remarks apply to the selection of plant equipment for the construction and maintenance of bituminous surfaces.

If bituminous concrete pavements are divided into three classes, depending on the character of the mineral aggregate, that is, first, those composed of so-called, one-size, crusher-run stone, second, those composed of combinations of stone and sand, and, third, those composed of graded sizes of broken stone or broken stone and sand, it will be seen at once that some machines on the market are adaptable for only one class of pavement, and others may be used for the construction of all classes, although, in certain instances, the overhead charges connected with their operation may not render them economical. Furthermore, when the large variety of solid and semi-solid bituminous cements which may be used for the construction of bituminous pavements, is considered, it is evident that the methods of applying these materials may make it possible to use certain machines and bar others. Such details as the heating of the mineral aggregate may also be a controlling factor in the selection of mixing machines.

In the case of mechanical distributors, the quantity of material required to be applied per square yard and the type and grade of the bituminous material essentially affect the selection. It is well known that, with many distributors on the market, it is impossible to distribute certain materials which may be used satisfactorily for a surface coat, and, with others, it is found impracticable to distribute the small quantities required in some methods of construction and maintenance.

Unfortunately, sufficient investigations have not been conducted by manufacturers of mixing machines or mechanical distributors to enable them to supply all the necessary information to prospective purchasers when definite requirements are submitted to them. As a result, there are many cases of purchases of machinery unsuitable for the work in hand and of unsatisfactory results in construction and maintenance accruing therefrom. Mr. Blanchard.

J. W. Howard, Esq.—The object of spraying is to get the material down into the surface layer before it becomes chilled. That is a mechanical problem. Coal-tars when cool are stiff and brittle, hence with their products it is essential to get them in quickly, while they are liquid and warm. Anything applied by the gravity method is likely to chill and set on top. Almost all asphaltic oils retain fluidity or viscosity, even when cool; therefore, the gravity system often works well with them. Mr. Howard.

High pressures on bituminous products cause the air to enter the products and stiffen them seriously by a so-called oxidation. In the pressure system, care must be taken that the pressure is not so high that it will force air into or through the mass of warmed-up, liquid, bituminous substances, as this permanently stiffens or oxidizes them.

Philip P. Sharples, Esq.*—The speaker believes that better work can be done by some form of pressure distributor than by gravity distribution. It depends, however, on the kind of material used. Some materials work much better with pressure distribution than others on account of being more easily liquefied. With certain kinds of asphalt it would be almost impossible, in the present state of the art, for a contractor to use a pressure distributor. Mr. Sharples.

In Boston a number of Alco trucks have been fitted up with Kinney rotary pumps which deliver the tar to the spreaders at a pressure of about 30 to 35 lb. per sq. in. They, however, are better adapted to seal coats and to surface treatment than to penetration work where a large quantity per yard is called for on the first coat. It has been the practice to use the same pressure on the first penetration coat, that is, putting on about 1½ gal. of tar materials in one coat, but using steam pressure in the tank and a hand hose and spraying nozzle for the distribution. A hose in the hands of a good workman produces very good results. It is absolutely essential to have a good man at the end of the nozzle, or unequal distribution will result. The seal coat may be applied to advantage by pressure spreaders spraying ½ gal. per sq. yd.

The truck is also used on surface coatings, both with hot and cold materials, with excellent results. Auto trucks are well adapted for

* Chief Chemist, Barrett Mfg. Co., Boston, Mass.

Mr. Sharples. central plant distribution, and can cover a territory within a radius of about 60 miles. The material can be kept hot for this distance without any difficulty.

Mr. Hubbard. PREVOST HUBBARD, ASSOC. AM. SOC. C. E.—The thermometer is recognized as an important part of the necessary equipment for plant control. It is rather surprising, however, to note the number of instances where, in the construction of bituminous surfaces and bituminous pavements, the bituminous material is heated in small kettles and no attention paid to the temperature of the tar, oil, or asphalt used. Many contractors and engineers in beginning their work start with thermometers as a part of their equipment, but, as a rule, they are soon broken. The work, however, is often continued without any further attempt to keep temperature records.

The common laboratory thermometer is not satisfactory for obtaining the temperature of large quantities of bituminous material heated in kettles. It is advisable, if not necessary, when obtaining kettle temperatures to use a larger thermometer, preferably one which can be attached to the sides of the kettle and will indicate at all times the temperature of the bituminous material in the kettle. Such thermometers can be purchased at reasonable prices, and have large scales which can be read at a distance, so that the kettle man may see at all times what temperature he is maintaining. For determining the temperature of heated mineral aggregate, the average thermometer is practically useless. If it is continuously thrust into and withdrawn from hot bituminous mixes, it will eventually crack and break, due to sudden cooling.

A thermometer has been designed recently which is preferable to any other that has come to the speaker's notice. It is made by electroplating the lower 6 in. of the tube and bulb of a glass thermometer with a heavy deposit of copper, which protects the glass from abrasion, but allows quick and accurate temperature registration. The thermometer has a sharp pointed bulb, and is made of heavy glass. It reads, from 50° to 500° or 600° Fahr. This thermometer is now manufactured by the Taylor Instrument Company, after a design by Mr. J. O. Hargrove, Inspector of Asphalts and Cements, of the District of Columbia.

Paper No. 1287

PHYSICAL VALUATION OF RAILROADS.*

By William J. Wilgus, M. Am. Soc. C. E.

With Discussion by Messrs. Maurice G. Parsons, J. Frank Aldrich, J. Shirley Eaton, C. P. Howard, M. H. Brinkley, Albin G. Nicolaysen, F. A. Molitor, Halbert P. Gillette, J. F. Willoughby, S. Whinery, F. Lavis, William W. Crehore, Alexander C. Humphreys, J. H. Gandolfo, T. Kennard Thomson, Charles S. Churchill, R. D. Coombs, Colin M. Ingersoll, Arthur M. Waitt, Stevenson Taylor, F. C. Hand, P. H. Norcross, Charles Rufus Harte, F. W. Green, R. S. McCormick, Charles Corner, and William J. Wilgus.

The Herculean task of valuing the railroads of the United States is of vital importance to the entire nation, whether viewed from the standpoint of rate regulation or its possible outcome, government ownership. The vastness of the interests involved and the effect that the result may have on social conditions, make imperative the adoption at the outset of underlying principles and methods which will appeal to the public and the Courts as being fair and equitable.

It is with the object of promoting a discussion that will be of aid to those burdened with the accomplishment of this task that the writer ventures to advance certain opinions which are the fruit of his experience in the valuation field.

---

* Presented at the meeting of October 1st, 1913.

BASIC PRINCIPLES.

There are several ways of determining physical value, depending largely on the purpose for which the result is to be used.

Sale Value.—In taxation matters, the sale value method has been used, right of way and real estate being taken at their assessed valuation, and other items at their depreciated or second-hand value, without the inclusion of overhead and development costs.

In New Jersey this method was adopted in compliance with the general tax law of the State, the expert in charge of the valuation stating in his report as follows:

"Since the real estate and personal property are to be inventoried and appraised separately from the franchise, it seems manifest that it is our duty to consider all of the thousands of parts and items of the property owned by each of the several railroads, entirely apart from their value as considered in the composite whole cemented together by the charter or franchise."

In referring to the fixing of land values, he says:

"We have the right to assume, however, that since the several assessors are elected or selected by the taxpayers of their respective communities, they must have had sufficient experience in land values to entitle them to assess the property in their respective districts, and that, therefore, they are the best available source of information concerning the going price or 'true value' of the land in their districts; and, since the several taxing districts are content to accept the opinions of these assessors as to the 'true value' of the property of individuals, corporations (excepting railroad corporations) and firms, we should give considerable weight to the opinions of the several local assessors when considering the 'true value' of land."

Also:

"No per cent. has been added to the value of lands in excess of the value in exchange for money, as near as such value can be determined by the exchange price of lands adjoining the lands of the railroad in each particular taxing district, and at each particular point where such lands adjoin railroad lands."

While the New Jersey procedure was proper under the conditions there prevailing, it yielded results entirely at variance with those obtained in other States where different theories have guided the appraisals.

Certainly, the sales value principle of treating the component parts of a property as uncorrelated items, at prices that they would bring

if thrown on the market, is not applicable to the ascertainment of the full value of the tangible property of railroads as going concerns.

Original Cost to Date.—In the Act of Congress that prescribes the alternative methods under which the Interstate Commerce Commission is to proceed, Original Cost to Date is named, in which the actual cost of property, as reflected on the books and records of the companies, is to be taken.

With rare exceptions, it is extremely doubtful that the books and records of the railroads of the United States will be found to be dependable for the purpose of ascertaining present-day fair values. Only in recent years have cost accounts been kept in a uniform and complete manner, and even then the almost universal tendency has been to understate charges to construction, and to additions and betterments. This is particularly true on systems that are the product of gradual expansion over terms of many years. Interest during the period of construction, organization and administrative expenses, supervision, freight charges, and the use of equipment on extensions of main line and branches, in many, if not the majority of, instances, have been largely or entirely absorbed in the running expenditures of the parent company, and are not reflected in the book costs. On the older lines the accounts of many of the constituent roads have been lost or are incomplete. Additions and betterments have been charged to operating expenses. Roads have been absorbed through foreclosure proceedings, and the cost has been entered on the books at figures much less than their original cost. In fact, all that can be said of the surviving books of the older railroad systems is that they show merely such portion of the original cost to date as is there recorded, and that, therefore, they are not proper for use in physical valuations, except in so far as they may be of aid in casting a side light on estimated costs of reproduction as of the present time. Moreover, the loss of old records on many roads, and incompleteness of records on others, would necessitate frequent departures from the general rule, with resulting inconsistencies and injustice.

Cost of Reproduction New.—The second of the alternative methods prescribed in the Act of Congress is Cost of Reproduction New. Under this theory of valuation, as generally construed, the configuration of the ground surface and other natural topographical conditions along the line are assumed to be restored and be as they were before the

railroad was constructed, but in all other respects the existing environment is taken as of to-day.

In determining quantities and values under this method it would seem essential that, as far as possible, the procedure should be duplicated that experience has shown would have to be followed, step by step, in the creation of a going railroad. Mere inventorying of the innumerable component items and the placing of a price on each will not give the cost of reproduction, because the intimate relation that the parts bear to each other and the cost of their assemblage into a connected whole are thereby ignored.

The impression prevails that the building of a railroad begins with the breaking of ground and ends with the driving of the last spike. The fact is that there are three well-defined and equally important stages that precede the successful completion of a solvent enterprise, the first and last of which are given but little weight in the usual estimating of cost.

First there is initiation. The plan has inception in the minds of men who are fitted by experience, acquaintanceship, resourcefulness, courage, and tact, to give it life and sustain it through many vicissitudes to final issue. Reconnoissances, preliminary surveys, and estimates of cost, revenue, and profits, are needed to demonstrate its feasibility. Tentative agreements are essential for the features that must be secured before publicity. Arrangements must be concluded for financing the project through underwritings or by sales of securities on a commission basis. Capable men must be selected for the administrative and engineering staffs. All this requires much time, often years, and considerable expenditures which the Interstate Commerce Commission has authorized as chargeable under its classification of "47, Interest and Commissions" and "48, Other Expenditures."

Next comes the constructive stage. This embraces final location, investigation of subsurface conditions, and surveys; the preparation of maps, plans, specifications, and estimates; the purchase and condemnation of rights of way and real estate; negotiations with other railroads for trackage and crossings, and with municipalities and towns for franchises and other privileges; the requesting of bids and the awarding of contracts; and then active construction by contract and company forces.

The acquisition of land and of rights from others is a slow and tedious process, fraught with delays and expensive litigation, and it is rarely safe to proceed with actual construction on important work until this step is concluded.

Construction proper necessarily would not be started simultaneously on all portions of a large system. The main stem would require first attention, followed soon by the important terminals, next the principal branches, then the lesser ones, and lastly the minor branches and spurs.

Expeditious construction of a great railroad system through populous communities does not admit of the awarding of small contracts, as is usual on minor extensions of a "going" railroad. Responsible contractors of wide experience, with followings of sub-contractors, must be attracted by the prospect of work of magnitude at remunerative prices.

Lastly is the educational and development stage, when the line is opened to traffic. Competent forces must be selected, organized, and trained to maintain and operate tracks, structures, rolling stock, and floating equipment. Errors of design and construction, as developed by operation, must be rectified. Equipment in consignments must be received from the manufacturer, "broken in," and assigned to varying duties. Traffic must be induced, economies studied, experiments tried, and the public brought to an appreciation of the new facilities. Stated differently, all parts of the new creation must be co-ordinated and thoroughly trained in their new duties before it is possible to handle successfully a great volume of traffic. This period of education, adjustment, and development, during which the earnings from operation would increase from nothing at the commencement to the full amount at the end of the period, varies, of course, with the nature of the country and traffic. Under the most favorable auspices, it usually lasts for several years.

It is evident that the mere inventorying of the items of a railroad as parts of an inert whole will not give due weight to the processes that experience has shown are essential to the creation *de novo* of a vitalized homogeneous system of transportation, equipped, manned, and trained for the same character of service that it now performs. The problem should be approached in much the same spirit as in the actual organizing, building, and launching of a new railroad.

Cost of Reproduction, Less Depreciation.—The remaining method mentioned in the Act is Cost of Reproduction, Less Depreciation. For rate-making purposes it does not seem to the writer that the physical depreciation should be deducted from the cost of reproduction new. Both law and practice have determined that all expenditures for renewals and repairs should be charged to working expenses, and not to capital; or, stated differently, normal depreciation is not to be treated as a wastage of capital, but as an element in the cost of operation that is covered by the rate.

That any other course would be improper and even illogical is at once apparent when it is realized that in any subsequent reappraisal, say a year hence, the inclusion therein at full value of a renewed item that appears in the appraisal at its depreciated value, practically would amount to the capitalizing of a renewal expenditure that had been charged to income.

In fact, the Act, in requiring that valuations shall be revised from time to time as improvements or other changes are made, in effect prohibits the deduction of depreciation, as otherwise the constant addition of amounts expended in the replacement or renewal of items that had been included in the valuation at their depreciated price, would be a violation of the rule of the Interstate Commerce Commission that operating expenses should not be charged to capital.

For instance, expensive coal pockets which will cost, say, \$600 000 to renew, may be worth a nominal sum in their present-day run-down condition. The adoption of a depreciated figure would mean that when the structure is rebuilt, say, next year, \$600 000 would be added to the valuation, although correct accounting would demand that the entire cost should be charged to operating expenses.

The conclusion seems warranted that, for rate-making purposes, depreciation should not be deducted from the cost of reproduction. It is plainly a liability of the stockholders, partly offset by any reserves that may have been established for that purpose, and should be given due weight in determining a railroad company's net profit and loss account. Of course, in the case of Government acquisition, this feature would require due attention, for the reason that the purchaser would be assuming the stockholders' burden of future restoration of depreciated items.

Summary of Basic Principles.—If the foregoing reasoning is sound, it is evident that the selection of the underlying basic principle must be guided by the purpose for which the valuation is made.

The sale-value method, while used in certain instances where the general taxation laws thus require, is inapplicable for rate-making and acquisition purposes because it does not take into account the features that mark the difference between an aggregation of dissociated parts and the same parts cemented together and pulsing with life as a going concern.

The original cost-to-date method is inadmissible, except as a side light on other methods, because the incompleteness and non-uniformity of past records are a bar to the making of accurate statements of full cost, and because the loss of such records on many roads makes impossible that universality of application that is essential to equity and fairness.

Cost of reproduction new, if estimated in such manner as to embrace all the steps that experience has shown are needed for the creation of a living, self-supporting organism, may be considered as a fair measure of physical value in connection with rate regulation; but physical depreciation, being an element of waste chargeable to operating expenses and therefore a stockholders' liability, is not deductible except in cases where the burden of restoring the depreciation is transferred to a purchaser.

LAND VALUES.

Even though the reproductive principle is accepted, there are many who contend that land values should be entered in the estimate at their original cost, or at the current normal market price of neighboring lands, without any increase for severance and other damages, or for the excess that railroads are compelled to pay for right of way.

Original Cost.—The "original cost" measure of land values is believed to be unfair, for two reasons: It ignores the increment that is enjoyed by all other property owners through increase in the population and prosperity of the country; and it would lead to the inconsistency of low original values on lines unfortunate enough to have preserved their land records, and high costs on adjacent lines where the absence of records would make imperative the use of present-day values.

Current Normal Market Prices.—That current normal market prices are not a proper gauge of the cost of reproducing railroad lands

is well known to all who have had experience in right-of-way matters. From a variety of causes, such as severance and other damages, plottage, and the psychological attitude of owners toward corporate purchasers, the prices paid by railroads are far in excess of normal neighboring values, in cities and towns the average factor ranging from $1\frac{1}{2}$ to 2, and in the country from $2\frac{1}{2}$ to $3\frac{1}{2}$. To ignore this condition is unjust in theory, and in practice would result in confiscation of property where actual expenditures for right of way on recently built lines can be proven to have been many times the cost that would result from the use of fictitious "normal market prices."

Reproductive Prices.—The conclusion seems warranted that strict equity can be served only by the adoption of one standard of land values applicable alike to all roads, and that the fairest standard is reproductive cost, which, as its name implies, calls for the estimated cost of reproducing the lands in each locality at the present time, taking into consideration all the elements which are known to have a bearing on the purchase of railroad right of way and real estate, including costs of acquisition.

This method guarantees equal consideration to the older lines and to those more recently built, avoids the dangers of confiscatory action, and gives due consideration to the facts that are known to enter into the purchasing and condemnation of lands for railroad purposes.

Lands Held in Reserve.—Recognizing that the erection of manufactories and other buildings, the opening of new streets, the laying out of parks, and the making of other costly improvements in the neighborhood of railroads, as well as increases in the values of adjoining property, will make the future acquisition of lands for the expanding needs of common carriers difficult and expensive, if not impossible, it has been customary for railroads to exercise foresight in the purchase of surplus lands at crucial points. It seems that lands in good faith so held in reserve for future use, are necessary for the proper performance of the duties of the railroads as common carriers, and, therefore, should be included in the valuation.

Inventorying and Pricing Measurable Items.

A physical examination of a railroad at once reveals a multitude of items which are patent to the eye and, therefore, may be termed "measurable items."

Interstate Commerce Commission Classification.—To estimate properly the cost of reproducing these items in place, as parts of a connected whole, it is exceedingly necessary that they shall be listed in such a manner that their relation to each other will be apparent; and this can be best done by adhering strictly to the classification of expenditures for road and equipment, as prescribed by the Interstate Commerce Commission. In fact, this procedure is imposed under the terms of the Act.

A number of valuations have generalized their treatment of the data embraced under the primary accounts of the Commission, with results that will not bear analysis. For this reason it is essential that every road item should be entered under its proper sub-primary account, exactly as would be done in the building of a new line. Bunching items together at lump prices will not accomplish this result.

Tentative Prices.—By inventorying all parts, with a view to their relation to each other during the process of construction, and by adhering strictly to the Interstate Commerce Commission classification, it is possible to determine in advance of the field work a list of tentative prices for all the items chargeable to each of the sub-primary accounts that actual experience has shown will be encountered.

As conditions on many railroads in various parts of the country differ widely, each locality requires special study in conjunction with such records of actual cost as may be available. Based on this study, a tentative price list may be adopted for the general information and guidance of the engineer in direct charge of each railroad subdivision. Such prices would be modified by him whenever local conditions made that course necessary, and in such cases his reasons for the modifications should be given for *visé* by the engineer in general charge.

In fixing tentative prices, due consideration should be given to many elements of cost which are of a temporary nature during construction and are not always apparent in after years, as, for instance, salaries and expenses in connection with the acquisition of lands; temporary trestles to facilitate track-laying in advance of the erection of bridge superstructures; preliminary surfacing of track for the preservation of rail from injury pending final ballasting; and transportation of men, tools, and material to points of distribution, the expenses of which are best incorporated in the unit prices rather

than to attempt to segregate them under Interstate Commerce Commission Account 32.

Owing to wide fluctuations in the costs of labor and material, the practice of adopting unit prices that will be fair averages over a period of several years has been followed extensively. This is undoubtedly the proper course, with the exception of items that have shown a constant tendency in one direction, as in the cases of lumber, piling, ties, and many classes of labor. In the latter instances, it would seem that current instead of average prices should be adopted.

Overhead Costs.

(Exclusive of Interest During Construction.)

As already stated, the inventorying and pricing of measurable items by no means yield the full cost of reproducing a railroad.

The necessity of providing means for cementing together these items is recognized by the Interstate Commerce Commission through certain accounts in the classification of expenditures for road and equipment, viz.: 1—Engineering; 35—Earnings and Operating Expenses during Construction; and 43 to 48, inclusive, General Expenditures.

An estimate of the cost of a railroad also requires an allowance for contingencies, which the fallibility of the best of engineering forecasts has shown to be necessary to cover omissions, errors, and uncertainties.

In the aggregate, these overhead expenses constitute a large percentage of the total cost.

Engineering.—It should be borne in mind that Interstate Commerce Commission Account 1 calls for engineering expenses in connection with Road Items 4 to 31 only, and does not apply to Items 2—Right of Way and Station Grounds, and 3—Real Estate, nor to Items 37 to 42, inclusive, Equipment.

Contingencies.—Despite the utmost care in estimating, experience has shown that final costs are invariably far in excess of preliminary forecasts, unless a percentage is added to cover a multitude of contingencies that arise during the prosecution of work.

An honestly prepared estimate never over-states quantities, but, on the contrary, omits many which are overlooked or escape attention.

Claims are made by neighboring land owners, employees, contractors, and others that frequently involve lawsuits.

Condemnation proceedings result in awards for damages far in excess of usual anticipations.

Floods, wash-outs, and errors of employees cause added expense.

Delays are sure to arise that enhance costs, as, for instance, through strikes, court proceedings, and difficulties in securing labor and materials, and also through increased interest charges pending the time of final completion.

Finally, there is always the danger of rising markets for material and labor, and of a scarcity of high-grade contractors.

Of recent years there has been a growing appreciation of the necessity of adding for contingencies not less than from 15 to 20% to carefully prepared preliminary estimates of cost. The instances are many where enterprises have under-estimated their cash needs, through inadequate allowance for this feature, with disastrous financial results.

It has been said that the knowledge gained from the study of a completed railroad largely eliminates elements of uncertainty. This is true of such features as adequacy of waterways, miscellaneous items often forgotten or overlooked in a preliminary estimate, and, to some extent, nature of foundations and classification of excavation; but the largest elements of chance still remain, such as claims, delays, rising markets, scarcity of competent contractors, omissions, inflated land values and damages, complications in connection with the elimination of grade crossings, and the nature of foundations, of which, on the majority of the older roads, little authentic information now exists.

There are also the further items, usually unprovided for elsewhere, of cost of acquiring lands; the expense of organizing maintenance and operating forces pending the commencement of regular operation; and expenditures for engineering, inspection, and "breaking in" of rolling stock.

General Expenditures.—In the words of the Chairman of the Public Service Commission of New York in the Rochester, Corning, Elmira Traction Company decision:

"When the amount of the actual cost of the physical construction of the proposed road has been determined we are still far from having determined the amount of capitalization which should be allowed. There are many elements of cost attendant upon bringing into existence of a new railroad additional to the cost of mere physical construction. Some of these elements may be enumerated as follows: (1) expense of organization, (2) incorporation tax, (3) expense of

obtaining a certificate of public convenience and necessity, (4) preliminary engineering expenses, (5) expense of procuring the authorization of issue of stock and bonds, (6) expense of marketing the securities, (7) discount upon the bonds provided they cannot be sold at par, (8) interest upon the bond issue during the period of construction and prior to the beginning of operations, (9) compensation of officers of the road during the construction period, (10) incidental expenses during construction period, (11) expense of obtaining local franchises and consents.

* * * * * * * *

"Another subject of great interest and importance is the compensation, if any, to which the promoters of the enterprise should be entitled for their services. Promotion has been so extensively abused and has been so universally used as a cover for abuses in capitalization that it has come to be regarded as a term of reproach and as a device to work schemes of robbery upon the investing public. No reason is apparent why this should necessarily be so. The honest services of a capable promoter are indispensable to the flotation of every comprehensive and far-reaching scheme of development in the railroad world, or elsewhere. A clear vision to see opportunities, ability to demonstrate them to others, and energy to push to completion works untried but of great moment, are indispensable to material development and should be fairly and even liberally rewarded by the public which receives the benefit of those works. Such rewards, however, should be put upon a clear basis of business principle, should be of sufficient magnitude to encourage rather than discourage enterprise, and should not be so great as to make exorbitant demand which is perpetual in its nature, upon the community to be served. They are to be treated simply as just payments for services performed for the corporation, which services are valuable and in many cases even indispensable. Such services should be paid for upon the basis of what they are fairly worth, having regard to all the circumstances of the case

"These observations are so elementary that further elaboration of the principle involved should not be necessary. * * *"

The Interstate Commerce Commission classification of expenditures for road and equipment provides for the charging of general expenditures to the following accounts:

43—Law Expenses;

44—Stationery and Printing;

45—Insurance;

46—Taxes;

47—Interest and Commissions;

48—Other Expenditures.

It has been usual in the valuation of public utilities to fix arbitrarily a percentage of the total cost to cover these items, but it seems possible to make an analysis of these charges and thereby reach a result that may be said to have a logical basis.

Law expenses, stationery and printing, and insurance may be estimated by taking the aggregate annual current expenses for these items on a given railroad and making a suitable allowance for the additional expense that would be probable under the conditions of construction, as compared with normal operation, for one-half the adopted total period of construction from the inception to the final completion of the enterprise.

Taxes during the constructive period may be taken at the current annual amount for one-half of the period extending from the date of commencement of right-of-way purchases to the time of commencement of operation.

Discount on bonds by many is not considered to be properly chargeable to cost of construction, on the theory that pure discount is equivalent to an adjustment of the interest rate to current market conditions. A banker's commission for the sale of securities, however, should be included. Payment for the services of those undertaking the sale of stocks and bonds seems to be just as legitimate and necessary as compensation for other services incident to the carrying out of the project.

"Other expenditures" may be obtained by taking the current annual cost of salaries and expenses of general officers and clerks for one-half of a period extending from the commencement of right-of-way purchases to the commencement of operation. In addition to this there would be the further payment properly due to those who, through their initiative, originality, ability, and assumption of responsibility of final success, would give life to the enterprise. The propriety of making this allowance is well expressed in the above-quoted opinion of the Chairman of the Public Service Commission of the State of New York.

Interest During Construction.

It is generally conceded that interest on money during construction is as much an element in arriving at the cost of the reproduction of a railroad as expenditures for any other purpose in achieving the same result. Payments for the use of money are in principle not different from payments for labor, or materials, or right of way.

During the process of construction of a new enterprise there is no fund on which the company can draw for interest payments, except interest-bearing borrowings supplemented by such net earnings as may result from operation during that time; and hence the capital raised must be sufficiently large to cover all items of cost, including interest upon itself, and "interest on the interest," up to the point of final completion of the road in running order.

Methods of Calculating Interest.—Although the propriety of including interest on money during construction as an element of cost is thus recognized, the tendency has been greatly to under-estimate the amount.

It has been customary to take the estimated cost at the adopted rate of interest for one-half of the assumed period of construction. This treatment is on the theory that the expenditures will increase in a constant ratio or straight line, from nothing at the beginning to the full amount at the end of the constructional period; that money advanced to the company is non-interest-bearing until actually disbursed; and that no interest is paid on the interest payments.

An analysis of the conditions that actually obtain in the building of a large railroad shows that the usual method of calculating interest charges yields a result very much lower than would actually occur in a reproduction of the system, for the following reasons:

1st.—Expenditures do not increase in a constant ratio. In the preliminary stage the rate of expenditures is small. Then there follows a marked rise because of heavy right-of-way payments, followed by a somewhat decreasing rate. Finally, the rate again increases by reason of large payments for equipment. The usual result is a much larger volume of expenditures in the early stages of the work than appears from the use of the straight-line method.

2d.—The securing of capital on a basis that will assure its delivery exactly as needed for disbursement during the progress of the work is not practicable. Stringency in the money market or other unforeseen contingencies make imperative the possession by the company of ample funds to bridge over temporary crises, even when the funds are supplied through banking houses of unquestioned strength. Either the entire amount must be taken at the time of financing, or the capital must be paid in annual installments in advance. In either case the

unused surplus over current needs is loanable at rates materially less than those paid by the company, the effect of which is an addition to the burden of interest charges during construction.

3d.—Interest charges must be paid from the capital, which itself is interest-bearing, and therefore it is not proper that interest on the interest should be omitted from the calculation of this item of cost.

Summarizing, the ordinary method of calculating interest charges usually produces an amount that is too low, by reason of the failure to take into consideration the heavy right-of-way expenditures in the early stages of the work; by reason of the neglect to include interest on unused money awaiting active use; and by reason of the omission of interest on interest.

Rates of Interest.—The rate of interest paid on the money invested has been usually taken at 6%, on the theory that the enterprise would be financed one-half on bonds bearing 5% and one-half on stock entitled to 7%, both bringing par on the market. Many examples can be quoted to show that this rate is conservative.

The rate received on balances placed on time loans may be taken at from 4 to 6%, and on call loans at from 2 to 4 per cent.

Time of Construction.—The assumed periods of inception, right-of-way purchases, active construction, and traffic development should be based on conditions as found on the particular railroad under consideration. On a complicated system, the time required for the acquisition of right of way and for the construction of the more difficult lines should govern, and the assumed date of commencement of active work on the less important lines and branches should be advanced so that sufficient time only will remain for their completion when needed for the initial operation of the system as a whole. Industrial spurs as well as equipment may be assumed to be supplied during the final stage when traffic is being gradually induced. By treating the subject in this manner the building of the various sections and the delivery of equipment will be co-ordinated with a view to completion only as needed, and the undue expenditure of interest on inactive capital thereby will be avoided.

Graphical Analyses.—To assist in determining the lengths of the different stages, and in ascertaining aggregate capital requirements and net interest payments as the work is assumed to progress, graphical

analyses will be found to make this important subject clear and conclusive.

Earnings During Construction.—Proceeding on the theory that the full current net operating income of a railroad will be realized at the end of the last stage of construction, it is, of course, proper that the capital invested should be credited with the net earnings enjoyed during that stage. These may be taken at the full current net earnings of the company for a length of time equivalent to one-half of the educational and development period, except on roads where losses instead of profits may be fairly estimated for the development period. In the latter instances it would seem proper to consider the net losses as legitimate charges to the cost of creating the enterprise.

Working Capital.

That working capital is absolutely necessary for the proper running of a railroad is well shown in the following extract from the opinion of the Chairman of the Public Service Commission of New York, in the Rochester, Corning, Elmira Traction Company case:

"In addition to the foregoing matters, there should be provided upon the commencement of operation a fair and reasonable amount of working capital. The operation of the company can be continued with far greater efficiency, more to the satisfaction of the public, and with better results to the stockholders, if it has at all times in its treasury a working capital sufficient and adequate to meet the requirements of the road. Experience has demonstrated this so many times that insistence upon it or elaborate demonstration of its truth is not required at this time."

Working capital represents money permanently non-productive except through earnings derived from the transportation of passengers and freight. It includes cash held in readiness for the prompt payment of pay-rolls and vouchers, money tied up in bills receivable, and money invested in "stock on hand." The average amount may be ascertained from a study of the annual report of the railroad company.

Depreciation.

Depreciation, modified by the appreciation of those parts that improve with time, should be based on actual conditions and on suitability for continued use. As a rule, several types of depreciable and appreciable property will be found on a railroad.

Bridges, Buildings, etc.—Structures like bridges and buildings, fundamentally sound and good for an indefinite continuing life, may have their depreciation measured by the estimated expenditures required to put them in 100% condition. Generally speaking, obsolescence in such instances is believed to be too speculative for consideration.

Rails.—Certain items, like rails, are good for an indefinite continuing life, during the early stages of which there is a gradual diminishment of value followed for many years by fixed values. Rails usually pass through several stages before they are unfit for further use in track. First, they are utilized on the more important lines until their condition becomes such as to make them unfit for high-speed passenger service. Then they are transferred to lines of minor traffic, or to sidings and yards, where they may remain for an indefinite period. Manifestly, it is improper to attempt to measure their depreciation on an arbitrary mortality basis, as in some instances the character of the traffic may be such as to wear out the rail in one-half or one-third of the assumed ultimate life, and in other cases the traffic may be so light as to permit the retention of the rail in service for possibly twice the assumed ultimate life. Therefore the depreciation of the rail in each instance must be judged by its actual condition and the kind of traffic that it bears. Commercially considered, there are three classes of rail: new, relayer, and scrap. Between the first two there is a gradually decreasing range of value from the new to the relayer price, the difference between them being spreadable over the average period during which it may be assumed that the rail will be suitable for the higher classes of service. Further depreciation below relayer value will depend entirely on actual conditions as the material approaches the point where it is removable as scrap.

Ties and Timber Trestles.—In a number of cases experience has shown that a fairly definite life may be determined. Ties, for instance, from a study of the renewal records of each company, will be found to have an average life, and the average percentage of depreciation of all the ties in track will depend on the time of year when the observations are made. Timber trestles will be found to have average lives, depending on the kind of material of which they are constructed and their location and purpose. In some instances the trestle may be made as good as new by the replacement of a few of the more perishable parts of the structure, and in other cases an entire renewal will be required.

Between these limits, depreciation should be measured by the proportion of the total life of the structure that has expired.

Equipment and Machinery.—With rolling stock, floating equipment, and shop machinery and tools, obsolescence as well as decrepitude should be taken into account, as past experience has proven that there is a well-defined period of economical life beyond which continued use is wasteful or unproductive. In treating this class of depreciation, more than ordinary experience and judgment are required, because of the fact that on the character of up-keep is dependent the economical life of the item that is under consideration. Therefore it is rarely possible to adopt any fixed rule that will be applicable under all conditions.

Graduation and Ballast.—Embankments in the course of time undergo solidification following impact of rolling stock and the action of the elements. This seasoning results in appreciation that may be gauged by the estimated cost of obtaining practically the same desirable condition at the time of the construction of the road. This cost will depend on the availability of water for consolidating purposes, the nature and quantity of material, and the degree to which the act of solidification will interfere with the ordinary manner in which the embankments would be built.

Excavations on a new railroad are known to give much trouble from slides and filling up of ditches, entailing constant labor, often with the use of work trains, until the surfaces of the cuts adapt themselves to conditions, or, in other words, become seasoned. In the case of embankments it is possible to measure appreciation by the equivalent cost of compacting them artificially, but it is not so easy to fix definitely the value of appreciation in excavations; however, a close approximation may be made by estimating the cost of work train and other service for an assumed period of time, taking into account, of course, depths of cuts, their age, and the nature of the material.

Where slopes for fills and cuts in the course of time have become grassed or otherwise covered with vegetation which protects the surface, allowance for appreciation may be made on the basis of the cost of the adding of these items in the course of construction.

For a considerable period after tracks are first ballasted, more or less trouble and expense are involved in preserving line and surface, particularly during periods of wet and frost. This is due to the working of the ballast into the roadbed, the filling of interstices from beneath,

and to the fact that the ties have not become solidly embedded in the ballast. As a consequence of these conditions, extra labor is required constantly, to readjust the track, and there is an absence of the smooth riding of trains which is so essential to fast passenger service and to the minimizing of repairs to track and equipment. As time goes on, the track is raised on new ballast, so as to maintain it at its original height, and the original ballast is pressed or settled downward into the roadbed, where it remains as a firm, semi-porous substratum or blanket to protect and sustain the overlying newer ballast. This newer ballast is the visible portion which appears above the top of the shoulders of the embankment and is usually measured and estimated as ballast. The older or concealed ballast is incorporated in the roadbed, and though it is not measured and estimated as such, its value is reflected in the appreciated worth of the part that is measured and estimated. Experiments have shown that a thickness of 24 in. beneath the bottom of the ties is necessary to distribute the weights of rolling stock properly, and therefore appreciation of ballast may be considered as being measured by the cost of the concealed portion to a maximum depth of 24 in. below the bottom of the tie, less the cost of the roadbed material thereby replaced. Of course, if ballast is dirty and requires cleaning, the approximate cost of forking it over or otherwise cleaning it may be deducted from the appreciation arrived at as above.

Organization of Valuation Corps.

With the general principles settled which are to govern the work, the organization of the valuation corps next commands attention. Viewing the problem in the same spirit that guides the actual creation of a going railroad, it is evident that the mental attitude of the leading members of the corps must be in harmony with the practices that obtain in the inception, construction, and initial operation of the enterprise. Consequently, they must be men of broad experience in their respective fields, capable of adjusting rules and prices to conditions as they find them in each particular instance. Mere inventorying, without the detail and constant supervision of experienced engineers, will produce results which will be easily attackable in court.

In a word, the problem is one that calls for a high order of engineering skill in both rank and file, so that the outcome may reflect all the processes which have a bearing on the final cost of a live railroad.

Valuation of Road Items.—Rather than subdivide the work under a number of engineers having charge of separate subjects, such as grading, bridging, and track, the writer believes that territorial divisions or districts should be established, each in charge of an engineer capable of viewing his assigned territory as a whole, and of personally passing on the value and condition of all items in the light of their relations to each other, except those on which he will require the advice of special experts. In addition, it may be said that territorial valuation has the merit of readily lending itself to the segregation of results so that they may be made available for a variety of purposes, as, for instance, in estimating the cost per ton of transporting commodities from various originating points to destination, and in verifying values used in various taxing districts.

Although engineers with experience and ability in handling the work as thus outlined could personally pass on the majority of the items entering into way and structures, there are several features requiring the attention of special experts.

These consist of right of way and real estate, interlocking and signals, and shop machinery and tools. In addition, the engineer in charge of each district will at times need advice on other specialties, as, for instance, heating, lighting, and power plants in shops and enginehouses, and important or unusual structures.

Valuation of Lands.—The right-of-way and real estate expert should be a man of wide experience in the purchase of land for railroad purposes, having also an intimate knowledge of railroad land values in the section in which he is located. He should be expected to ascertain the current basic values of neighboring lands as a means of measuring the value of the railroad properties, make inquiries of local real estate agents and others familiar with the subject, and, in finally fixing values, take into account the factor in each case that experience has taught should be used as a multiplier in connection with railroad purchases.

It is believed that this method of ascertaining the reproductive cost of right of way and real estate, through the central agency of one having this comprehensive knowledge of the values of land purchased and used for railroad purposes, will avoid the inconsistencies and errors which are common where the work is entrusted to a multitude of local men unversed in the broader aspects of the problem.

Valuation of Equipment.—Rolling stock and floating equipment, as defined by the Interstate Commerce Commission, should each be placed in charge of an engineer of standing in his specialty. Each locomotive, car, and boat need not be viewed personally by the appraiser, but a sufficient number of each class or type may be inspected to fix their value and condition.

Forms and Tables.—The adoption of forms on which observations are to be recorded and results compiled, is, of course, an important step in the work. The forms should be inter-connected in such a way that it will be easy to trace backward from compiled results to the parent underlying data, and they should avoid generalizations which cannot be substantiated by facts as recorded in detail on the ground.

Tables and diagrams are also of value in facilitating field and office calculation of quantities, and as a check on arithmetical work.

Conclusion.

In conclusion, it may be said that the cost of reproduction new appears to be the only measure of physical value that places all railroads on the same plane, and the only one that provides for the inclusion of every element of cost that enters into the creation of a going railroad. If properly applied, it will give due weight to the duplication of lands, under exactly the same conditions as are known to prevail in actual practice; it will provide for the inventorying and pricing of measurable items in such a manner as to recognize their correlation and the varying local conditions that surround them; it will recognize the propriety of adequate charges for overhead costs, including engineering, contingencies, general expenditures, and payments for the use of money during construction, all of which are so essential to the assemblage and endowing with life of the component parts of the system; it will take into consideration net gains or losses during the final or development stage of reproduction; and it will not forget that working capital is as necessary to the success of the enterprise as other capital charges. The fulfilling of these conditions calls for engineering skill and experience of the highest class, not alone in technical fields, but also in the broader domains of administration, finance, and operation.

A physical valuation thus embracing every item of cost that enters into the duplication of facilities in full running order, equipped,

manned, and trained for the same character of service that they are now performing, may be said to include many of the intangible elements of going value which are so difficult, if not impossible, to measure in any other manner. There are, however, other elements of value, such as traffic productivity and operating effectiveness, that cannot be measured in this manner, and therefore are beyond the scope of this paper.

Whether or not physical depreciation should be deducted from the cost of reproduction new, may be said to depend on the purpose of the valuation. If its intent is the ascertainment of a price to be paid by a purchaser to whom is to be transferred the owner's liability as regards future renewals and replacements, then, beyond question, depreciation should be deducted; but, if the amount of capital invested is the point at issue, depreciation, being an element of operating cost and not a wastage of capital, should not be deducted.

DISCUSSION

Mr. Parsons.

MAURICE G. PARSONS, JUN. AM. SOC. C. E. (by letter).—Valuation, to-day, is the fashion, and rightly so, for only with absolute and complete knowledge of facts can justice be done either the consumer or the producer. Surely, this is a great subject, large beyond the ability of any one commission which has not the thorough support of the entire country and cannot rely absolutely on its assistants. The people, the corporations, and the Profession should most heartily welcome Mr. Wilgus' paper as an endeavor to clarify valuation views more fully and to secure the co-operation of all concerned.

It is interesting to note that here, again, the much-discussed subject of depreciation has come up. There is, perhaps, more written on this phase of valuation than on any other, very largely because, like will-power, it is a sort of composite; depreciation is made up, in part, of red lead, stomach, philosophy, bookkeeping, obsolescence, and the methods of treatment throughout. This divergence of methods causes much trouble. Any one of several logical processes will give correct answers to the question of depreciation, although certain steps in one method may differ entirely from similar steps in another.

The author has approached the subject of physical valuation in the large, showing that it is not a question of so many yards of earthwork, so many tons of steel; but that all parts of a railroad must be combined, fused, and vitalized, that they must be made a single working machine. That, however, is not all; the mere inventory of the physical property (if one may broaden the discussion beyond the limit set by the subject) is only a small part of the problem. Before a board can rightly take from one and give to another, it must have knowledge, not only of the physical value, but of the complete economic and financial history of the company. It must know the total cost of producing the commodity (which cost is at times greatly in excess of that of the physical plant) and the total profit derived from its sale. Promoters may embark in hazardous but necessary business during hard times, with the result of large financial loss in the early days; then again there may be absolutely no risk connected with the building up of the business. The development value may be practically nil. On the other hand, regardless of risks which have been taken, subsequent profits, whether great or small, may alter entirely the question of what equity the public has in the business. The real problem begins after the physical valuation is made, and necessitates a complete knowledge of the history of the company and of the financial and political situation during its life. As the physical value must be determined in a broad-gauge manner, so also the entire subject of rate-fixing goes deeper than mere consideration of physical value.

Mr. Parsons.

One question about which the writer has been thinking is: "Where may our theory of valuation lead?" May we not get back to the old labor theory of value, which held, for example, that if a man produced in one day a clock which kept perfect time, whereas another man labored equally hard for a hundred days in producing an inaccurate timepiece, this second man, nevertheless, was entitled to one hundred times as much wages as the first man. We cannot say that a utility is entitled to a fair profit on all the investment unless that investment has been wisely made, and we must judge past actions with leniency. On the other hand, although the best judgment may have been used, it is possible that business has almost entirely disappeared, and that the company is entitled to a rather high rate—to what the traffic will bear. Rates must bear some relation to the actual cash value of the service and to a proper return on judiciously invested capital. The germ of the solution of this question of policy (which allows a fair return on the actual investment which may be considered to measure the labor, and may bring us back to the old labor theory of value) is contained in the case of Smith *vs.* Ames, wherein it is pointed out that the rates as affecting the welfare of the corporation and the welfare of the people must be considered in the light of a complete history of all conditions. It is to be hoped that this general broad subject will be more elaborately discussed, for on that depends the fair rate. Necessary regulation of present-day business gets us into deeper water than the one-time automatic competition of small companies.

As the value of a property depends on the purpose for which the valuation is made, we have several sub-heads of valuation. First of these may be mentioned the physical value, determined by any one of several methods. Next, we may place the development or intangible value, consisting of various items not properly appraisable under the head of physical value, such, for example, as promoter's profit, legitimate costs of franchise, legal and engineering expenses, certain property rights, present value of past deficits, etc. Thirdly, the business value is the net income capitalized at the current rate of interest. The fourth, or going, value is sometimes used synonymously for the development value, or again with business value. It seems, however, that this is in reality a value by itself, differing from those already mentioned, and that it can very properly be defined as the difference between the business value and what the same investment would earn in a bank. In other words, if a capitalist chooses to let his money lie idle—chooses to be unenterprising—he gets a certain amount of interest. If, however, he sees fit to invest this money in a business, to promote a project, guide it safely through the development stage, put it in a good running order, and make the organization as a whole a single living unit—a going concern—he is entitled to more interest;

Mr. Parsons.

he is entitled to a fair return on the investment under the particular conditions which he has met and conquered, and the going value is that excess which the business earns over and above what the same money would earn had he chosen to leave it in a bank. The going value might quite properly be defined as the difference between the business value and the idle value.

Mr. Aldrich.

J. FRANK ALDRICH, ESQ. (by letter).—Mr. Wilgus' paper is the "last word" on this present-day subject, and although the writer will confine his remarks to a discussion of the land element involved, it is difficult to see how he is going to raise many issues in the field covered by this paper; for, after some ten years of experience by valuation engineers and a pretty general discussion of the subject, the author has succeeded in eliminating a vast amount of theory and undigested argument—going directly to the meat of the proposition—and from his record as a practical railroad builder and appraiser has evolved basic principles which are both logical and sound. The writer does not mean by this that the subject is beyond the realms of controversy in detail, but as to the hitherto mooted questions of reproductive value, overhead charges, depreciation, etc., the author is most convincing and in accord with the best authorities on the subject.

As with many propositions of professional interest, the opportunity exists for wide-spread discussion, which is sometimes carried to a point of beclouded mental vision. The sooner the subject reaches the practical stage—where justice to all concerned will be the key-note of discussion—the sooner will there be harmony of action between those who, on the one hand, are honestly striving to do exact justice to the general public, and those who, with equal zeal, represent the railroads.

With the railroads (it has been suggested) this public valuation is to be a "two-edged sword," for, if the result is satisfying as a basis for rate-making, how will it operate when it comes to matters of taxation? The writer does not agree with some authorities: that there cannot be one valuation for the one and another valuation for the other. Bear in mind that these remarks are confined, as closely as practicable, to the element of land values (no inconsiderable part of the whole), and when R. A. Thompson, M. Am. Soc. C. E. (one of the Board of Engineers recently retained by the Interstate Commerce Commission under the Adamson Act), asks: "Is there any logical reason why a valuation for this purpose [the issuance of stocks and bonds] should not also serve—as far as it pertains—as a basis for taxation or for regulating freight rates?" and again: "as far as the State is concerned and to be consistent should not one valuation serve all purposes?" the writer answers, to both queries, emphatically, "no"! If an individual or corporation decides to build a railroad, he, or it, must acquire a right of way, which it is conceded will cost per acre,

Mr. Aldrich. through the country districts, from two to five times the normal acreage values of adjoining land. The fact that it costs this amount more, does not make it worth more, and it should be assessed (for taxation) at what it is worth, not at what it has cost. The reasons for its costing more to the railroad will not be discussed here, for that is now axiomatic and elementary. It is enough to say that it does cost more, as every one who has had broad experience in buying right-of-way property for railroads knows; and it would be a gross injustice, as well as a blunder, to tax the strip of land used for right-of-way purposes at its cost, say, $100 per acre, when the adjoining land is assessed at $25 per acre.

Mr. Thompson cites the Texas valuation, where he says his experience as Appraising Engineer for more than 10 years with the Texas Railroad Commission confirms his belief that, in the absence of actual figures of cost, right of way and other real estate should be appraised at but little in excess of the market value of abutting property, and adds: "the conditions under which the railroads were built in Michigan, Wisconsin, Iowa, and Minnesota cannot have been radically different from those in the southern and western states."

Now, let us see: In the Michigan Appraisal* two illustrations are given to indicate the factor that should be used for reproductive values:

1.—The Pere Marquette Railroad, in Montcalm County, paid an average price of $135.19 per acre, and the 1900 appraisal showed an average of $29 per acre on the 918 acres appraised........Factor, 4.66

2.—The Grand Trunk Railroad paid $491.13 per acre for 63.2 acres, and the 1900 appraisal showed $61.44, or only one-eighth of the actual purchase price..Factor 8

Twenty-three illustrations in fourteen counties showed that the average cost of lands was from 230 to 726% higher than the 1900 appraisal, and this, too, "after the 125% and fixed charges had been added" to the appraisal values.

In Wisconsin, the late W. D. Taylor, M. Am. Soc. C. E., the State Appraiser, said:

"In farming lands, small towns, and suburban and residence property, the right-of-way value was taken to be 250% of the market value for other purposes," and notwithstanding Mr. Thompson's conclusion "that, in the absence of actual figures of cost, right of way and other railroad real estate should be appraised at but little in excess of the market value of abutting property."

Mr. Thompson says: "For rural property, the ratios used by Professor Taylor in the Wisconsin appraisal appear to be quite fair."†

In Minnesota, Appraiser Morgan's findings (after employing several special agents who made a study of transfers and assessed values over the State) were, that in the State at large, exclusive of the St. Paul,

* *Transactions*, Am. Soc. C. E., Vol. LXXII, p. 57.

† *Transactions*, Am. Soc. C. E., Vol. LXXII, p. 205.

Minneapolis, and Duluth Terminals, a multiple of 3 was proper, while in St. Paul he used $1\frac{3}{4}$; in Minneapolis, $1\frac{3}{8}$; and in Duluth, $1\frac{1}{4}$. Mr. Aldrich.

Professor Taylor thought city property should be put in at 133% of market value in strips of 100 ft. width or less, and at 110% where the land was owned in blocks or in width greater than 100 ft. It is evident, however, that no "hard and fast" rule will apply to all parts of the country. Varying conditions appear along different lines, even in the same State. As stated by Henry Earle Riggs, M. Am. Soc. C. E.:*

"It is comparatively simple to fix within very close limits the reproduction cost of tracks, bridges, locomotives, or any of the other elements of physical valuations. Not so with the land."

And again:

"It is impracticable entirely to eliminate differences due to error of judgment on the part of appraisers. Where these differences do occur, experience must be the governing factor."

Were the records complete, an abstract of cost prices to the railroads, together with transfer considerations of adjoining land, and assessed valuations, the problem would be simplified, but, except in isolated cases, such records are not available, and the appraiser must be guided in large part by his or others' experience in the actual purchase of rights of way and other real estate for railroad use.. He must be fortified with ample local testimony as to basic values and the individual knowledge of local real estate agents or railroad employees who have personal information as to actual transactions. When practicable, he should examine recorded transfers at the county seats for a number of years back, and take notes concerning the assessed valuations on properties contiguous to the railroad. All this collateral information, including the names and addresses of local authorities, should be carefully preserved and indexed for ready reference. As Mr. Wilgus indicates—land valuations should be directed from one central head, from one whose experience in acquiring property for railroad use (whether by purchase or through condemnation proceedings) has given him the fundamentals which cannot be ignored in the fixing of reproductive prices.

The appointment of local appraisers has not resulted satisfactorily. Fixed opinions or local prejudices frequently exist among appraisers of good repute, and lack of harmony is bound to show in the returns. A well-drilled force of assistants, organized and directed by the chief appraiser, will produce the best results, and, as the author well says, "avoid the inconsistencies and errors which are common where the work is entrusted to a multitude of local men unversed in the broader aspects of the problem."

* *Transactions*, Am. Soc. C. E., Vol. LXXII, p. 139.

Mr. Aldrich. That problem is: What would it cost to reproduce for railroad purposes the land and other real estate now occupied by a given railroad—other conditions adjacent to and through the country traversed by it being as they are at present?

It is immaterial that the railroad itself may have been in large part responsible for the development which its own operation has brought to the surrounding property. It is inconceivable that the added values which have come to adjoining lands owned by A, B, and C should not be reflected in that owned by the railroad. The assessor certainly thinks it is. If one is in doubt about it, look up the record, for instance, of the increased assessment for 1913 on the terminal lands of the New York Central Railroad Company in New York City.

However, consider for a moment the question of "original cost" of rights of way. Unfortunately, the records of these purchases are not always—in fact are seldom—obtainable. In many cases they are not in existence, so that, to make any practical, general use of such data is out of the question; and, if they were available, their examination and tabulation would involve an amount of labor hardly commensurate with their importance to this subject. It will be interesting, however, to give a few examples which illustrate the elements to be reckoned with by the buying agent when he undertakes the purchase of rights of way. A recent case is that of a road now under construction just over the border line of Canada, which is not dissimilar to some of those on this side of the line. The road in question is to run along the north shore of Lake Ontario—through a fruit belt of much the same character as that traversed by a railroad on the south side of the same lake. The writer was considerably puzzled in fixing the reproductive values along the latter line, for there was but little information available covering the original purchases. The writer's assistant in that work was engaged later in valuing the right of way of the railroad on the north side of the lake and had access to the records of purchase. The twenty-five examples, Table 1, are from that record. The right-of-way agent states that his estimate indicates that the cost of the entire right of way will average between six and eight times the normal value of the adjoining land.

In the examples given in Table 1, improvements and what may be termed consequential damages are alone considered. The names and addresses of owners are known, but are omitted from the table.

If the true values of the land alone were represented in these data, the reproductive value would be represented by the percentages given, which, it will be noted, run from 200 to 800, but the right-of-way agent assures us that the prices allowed for the land alone were fully double their normal value.

TABLE 1.

Mr. Aldrich.

Example No.			Total cost.	Percentage.
1	3.15 acres of land	$200.00		
	Fruit trees	300.00		
	Moving house and shed	350.00		
	(Crossing reserved)		$800	$400
2	Land	300.00		
	2 wells	125.00		
	Moving house and shed	525.00		
	(Crossing reserved)			
	Fruit trees	250.00	1 200	400
3	1.67 acres of land	125.00		
	Angling field	100.00		
	Water cut off	50.00		
	Trees	75.00		
	(Timber reserved)		350	280
4	2.25 acres of land	135.00		
	Drainage, 80 maple trees	215.00		
	Angling farm	100.00		
	(Timber reserved)		450	333
5	1.55 acres of land	116.00		
	Angling farm	100.00		
	Water cut off	125.00		
	Moving fence	9.00		
	(Farm crossing)		350	300
6	3.3 acres of land	247.50		
	Angling farm	100.00		
	Water cut off	150.00		
	In lieu, farm crossing	52.50	550	222
7	1.75 acres of land	131.25		
	Severance from water	125.00		
	Angling farm	100.00		
	Fall wheat	13.75	370	282
8	3.6 acres of land	360.00		
	Angling—4 fields	200.00		
	Water cut off	150.00		
	Shade trees	40.00		
	(1 farm crossing)		750	208
9	1 [illegible] acres of land	150.00		
	Angling and changing fences	150.00		
	Water cut off	150.00	450	300
10	Land	200.00		
	Water cut off	100.00		
	Crossing inconvenience	200.00		
	Rocky land—crossing reserved		500	250
11	5.75 acres of land	550.00		
	40 apple trees	900.00		
	Gravel pit	50.00	1 500	273
12	2 acres of land	200.00		
	House and shop	600.00		
	80 trees	1 600.00	2 500	833
13	Land	100.00		
	10 apple trees	250.00		
	5 plum trees	60.00		
	Moving barn	50.00	460	460
14	Land	100.00		
	Apple trees	280.00	380	380

Mr. Aldrich.

TABLE 1.—(*Continued.*)

Example No.			Total cost.	Percentage.
15	House and land	$150.00		
	26 fruit trees	450.00	$600	$400
16	1.72 acres of land	525.00		
	Apple trees	1 080.00		
	Berry patch	395.00	2 000	381
17	3.03 acres of land	600.00		
	Apple trees	900.00	1 500	250
18	1.53 acres of land	200.00		
	Apple trees	450.00		
	In lieu, farm crossing	50.00	700	350
19	1.15 acres of land	150.00		
	Apple trees	250.00		
	Berry bushes	50.00		
	In lieu, farm crossing	50.00	500	333
20	3.17 acres of land	455.00		
	Water	300.00		
	Inconvenience	145.00		
	Crossing railway	100.00	1 000	220
21	1.5 acres of land	210.00		
	Apple trees	175.00		
	Strawberries	150.00		
	Damages	65.00	600	286
22	3.1 acres of land	465.00		
	In lieu, farm crossing	100.00		
	Deep cut through orchard	158.00		
	66 large apple trees	1 452.00		
	25 small apple trees	175.00	2 350	505
23	Land, 3.95 acres	450.00		
	Damages for cutting off water	350.00		
	Damages for crossing track	200.00	1 000	222
24	1.37 acres of land	400.00		
	House	300.00		
	35 apple trees	250.00		
	Well	100.00		
	Removing barn	80.00		
	17 plum and pear trees	70.00	1 200	300
25	0.92 acres of land	200.00		
	27 fruit trees	540.00		
	Strawberries	100.00		
	Damages to building	160.00	1 000	500

TABLE 2.

Town.	Acres.	Cost.	Average cost per acre.
West Haverstraw	22.45	$56 195	$2 500
Stony Point	104.77	187 670	1 800
Highland	105.26	183 985	1 800
Cornwall	35.78	71 530	2 000

Not any of this land is in West Point, which is a Government reservation. This company occupies under a lease from the General Government.

Mr. Aldrich.

It may be said that these are isolated cases, and represent but a small percentage of the entire right of way. This is true in part, but the percentage is not as small as might be supposed, on the other hand, not one of them was a condemnation case. Every one was a purchase, in which an agreement was readily reached between the buyer and the seller. Many owners are holding out for extravagant figures, and condemnation proceedings will follow; commissioners must be paid, and attorneys' fees will add to the expense. The railroads seldom "get the best of it" in cases of this kind, so that we may fairly conclude that the right-of-way agent's estimate of 600 to 800% in this instance fairly indicates the ultimate cost to the company.

A case in point to illustrate how difficult it may be for the appraiser to arrive at a fair value—or rather cost—of right of way, came under the writer's notice in appraising the lands of the West Shore Railroad in 1911. His assistant had gone over the road in advance, and reported an average valuation of the lands between West Haverstraw (north of Haverstraw proper) and Cornwall at from $100 to $300 per acre, basic, and had placed a reproductive value on it at from $300 to $750 per acre. The writer questioned his figures, and went into the matter carefully. Much of this right of way runs along the Hudson River at the foot of precipitous mountain sides—in fact, practically all of that which is in Orange County. Railroad construction there was most difficult. Above West Point there would seem to be but little actual value in the land. Fortunately, the writer was given access to the records of purchase (made in 1886) and was dumbfounded to find the total cost of these lands to be as given in Table 2.

The explanation of the high figures in Table 2 is to be found largely in the consequential damages due to severance, as the river was cut off from large estates by a railroad right of way at grade.

Another example which came under the writer's observation was on the Lehigh Valley Railroad near the Town of Wysox, Pa., where it became necessary to buy a house and lot to gain an additional 20 ft. of width for the right of way. The sum paid for this property was $10 000, and the house with the remainder of the property was sold for $5 000, making the 20-ft. strip (worth normally perhaps $500), cost the Railroad Company ten times its actual value. "Consequential damages," it will be perceived, is no small matter in railroad construction. A whole chapter might be given to this subject in view of the important and growing demand for the elimination of grade crossings. One example alone, which came under the writer's notice, may suffice for illustration. The New York Central Railroad paid, as its share, $3 132.98 and $32 592.87, respectively, for these eliminations at Seneca Street and William Street, in Buffalo. The total awards for these two crossings amounted to $7 531 and $65 185.63, respectively.

Mr. Aldrich. "Franchises and Street Crossings" is another branch of this subject to which much space might be given, but it is not the intention at this time to discuss any of these matters extensively. The writer has tried to give, as briefly as possible, some of the reasons "for the faith that is in him," and has given a few examples which have come to him through experience in this work to justify that faith.

The commonly accepted method of arriving at franchise value, through gross earnings and revenue, will hardly apply to railroad corporations, and it is perhaps of questionable propriety that any account should be taken of corporate franchise when applied to its charter. With this the writer has nothing to do; but, to ignore the element of value which applies to local franchises or rights to occupy or cross streets and highways, or even streams, would hardly be sound. Has the Park Avenue franchise, granted many years ago to the Harlem Railroad for an entrance into New York City, no appraisal value? Has the franchise which permits the New York Central and Hudson River Railroad Company to occupy Washington Street, Syracuse, for a distance of 1.2 miles no value?

The cost of a private right of way through either New York City or Syracuse, at the time these rights were granted, would have been comparatively insignificant. What is the right of way through the heart of Syracuse worth to-day, and how many millions of dollars would it take to purchase a private entrance to 42d Street from the Harlem River (more than 4 miles) if it had to be bought to-day? It might have been acquired for considerably less than $1 000 000 then —could it be duplicated for $25 000 000 now? Is genius and foresight to have no credit for risks of failure taken fifty or more years ago? Should capital invested in this particular line of business be singled out for attack and be deprived of the same natural benefits which come to other investments made in the same period?

The general rule to be followed in arriving at a just value of the space occupied by a railroad, at a street, or highway, or navigable stream crossing, is to multiply the average value of the abutting property on both sides by the area and divide by two, on the theory of joint occupancy by two interests—the public and the railroad. If the crossing be occupied by three interests (whether at grade or otherwise) then the divisor is 3, and so on. The same rule will apply to street or highway occupancy along and through the streets, unless sole occupancy of a given space is enjoyed by the railroad, when, if the right is perpetual, full value is taken.

Rights of way along and through streets, not at grade, should be estimated at one-third the value of the surface land.

These rules are quite general, and have been adopted as the result of careful thought and analysis growing out of study and experience in this feature of the work. All crossings not at grade are attended

by increased cost of construction to the railroads, and, if at grade, the cost of watchmen, or otherwise safeguarding them, puts an added burden on the railroad. If further justification be needed for including a value for public crossings in this estimate, it should be remembered that revenue is based on mileage to a large extent, and that, therefore, the value of every foot of right of way should be properly considered in some logical manner. Mr. Aldrich.

As to what lands, if any, owned by a railroad company are to be eliminated from consideration—in the matter of rate-making, for instance, the appraiser has nothing to do—that is a question for the Interstate Commerce Commission and the railroad company to settle. It is the appraiser's business to appraise all the lands of the company, and, in fixing his value, to differentiate between lands actually in use or needed for the operation of the railroad, and those which have been abandoned, such as depleted gravel pits, parts of original right of way, and even where surplus land has been acquired for future yard extensions.

It may be contended, for instance, that houses erected by the company, or purchased by it, for housing employees in the vicinity of shops or transfer yards, is not real estate proper to be included in a valuation for rate-making or of consideration in the issuance of the company's securities. However that may be, it will not affect the method to be used in its appraisal. It is "outlying" property, in any event. The company would not be confined to one particular location for such facilities, and its reproductive value would be the bare value of the land and the present depreciated (if any) value of the houses. Exhausted gravel beds or abandoned right of way would in most cases have but nominal value. Many similar instances could be mentioned, but common-sense judgment in most instances will govern. Large tracts of land purchased for yards, water supply, etc., are ordinarily acquired at a smaller figure, relatively, than right-of-way strips; on the other hand, "plottage" is an element to be considered, particularly in cities; so that no fixed rule will apply.

The question of land or money donations can be disregarded, for two reasons: First, because property is property always, and whether the railroad company or an individual has acquired lands without monetary consideration, or at a low figure, or as part consideration for the risks of investment, its value is an entity and cannot be ignored, either by the assessor or by the stockholder. Second, the practice of donations is a thing of the past—and we are dealing with the present. As part of the "original cost"—that is another proposition. There is no special rule for appraisal based on population that will apply. This will be disclosed by conferences with real estate men in different parts of the system. The attitude of owners will be found to be widely different in different places, but it will be found to be very nearly axiom-

Mr. Aldrich. atic that the more valuable the land required, the less the size of the factor which should be used to indicate its reproductive cost. This becomes evident when the company negotiates for a right-of-way strip through waste lands. An acre held by an owner here, or a few acres by another owner there, may be worth only $5 or $10 an acre, but, unless the wily farmer can get $50 per acre, it will, as a rule, go to condemnation, where the expenses will surely bring the cost up to the holding price.

Before leaving this subject, the writer should perhaps mention one or two additional examples to illustrate what has preceded. The normal value of land in Jersey City, where one of the shorter branches of the Lehigh Valley Railroad crosses the main line of the Pennsylvania Railroad, is 60 cents per sq. ft., but it cost the former company $3 per sq. ft. to acquire an easement under the latter line (through Court proceedings, if the writer remembers correctly), and later the Pennsylvania Railroad Company paid the same price for a portion of the Lehigh Valley property at the same point.

At another point, in Bayonne, it cost the Lehigh Valley Railroad $1.50 per sq. ft., when the normal values at that point were 25 cents per sq. ft. In Joliet, Ill., the following case came under the writer's observation: The right of way of the Rock Island Road was relocated, and it became necessary to tear down a 5-story hotel building, worth approximately $100 000. An appraiser, going over the line in later years, might have no knowledge of this, and no consideration would be given to it, yet it was a part of the cost to that railroad. In fact, other buildings at this point were either totally obliterated or there were consequential damages amounting to several hundred thousand dollars; and these are by no means isolated cases. Therefore, if the records were in all cases intact, a valuation based on "original cost," would be quite as satisfactory to the railroads as any reproductive valuation that could be made.

There are other elements of interest which enter into a proper consideration of the question. The rather perplexing problem of fixing a fair valuation on docks, piers, and water-front terminals will not be discussed at this time, nor the asset value of the virile railroad organization, which only time and a high order of executive control develops.

The "Physical Valuation of Railroads," as a science, is still in its infancy. The Courts probably appreciate this, and will no doubt be influenced in their rulings by the results which, as time goes on, will be worked out by engineers and students who are giving their time to the solution of these problems.

The Supreme Court decision in the Minnesota Rate Case was announced just as the foregoing had been written, and, after a careful reading, the writer finds no good reason for changing the views which he has just expressed. It does not seem possible that the land features

involved could have been properly presented to the Court. Like others who have discussed this problem, it does not differentiate between the terms "Value" and "Cost." The Court says: Mr. Aldrich.

"It is at once apparent that, so far as the estimate rests upon a supposed compulsory feature of the acquisition, it can not be sustained," and again, "it is also said that this price would be in excess of the present market value of contiguous or similarly situated property," but (it adds) "supposing the railroad to be obliterated and the lands to be held by others, the owner of each parcel would be entitled to receive on its condemnation its fair market value for all its available uses and purposes," and:

"Moreover, it is manifest that an attempt to estimate what would be the actual cost of acquiring the right of way, if the railroad were not there, is to indulge in mere speculation" and "the values of property along its line largely depend upon its existence" and, finally, "the assumption of its nonexistence, and at the same time that the values that rest upon it remain unchanged, is impossible and can not be entertained."

All of these arguments, with the exception perhaps of that contained in the last stanza, have been anticipated, and have been fairly met in the writer's consideration of the subject up to this point. There is force in the proposition that values based on present conditions might not obtain, in the event of the non-existence of the right of way. The argument is that the railroad, having been long established, has created values based on its very existence. Their determination, the Court holds, would be "wholly beyond reach of any process of rational determination." Much might be said on this phase of the question, but, the writer thinks, it is susceptible of demonstration that, as a rule, railroad terminals in cities tend to depreciate the value of contiguous property. Good examples of this may be found in Chicago and Buffalo, where real estate men know that the least desirable—and consequently those which have the lowest values—are those properties which surround the railroad terminals. The writer knows of no city, in fact, where this does not apply.

The location of a railroad right of way through the country is usually determined by natural laws, and the farm values affected by its construction extend, ordinarily, for some distance on each side of it, but farmers state that the effect of the building of the right of way immediately adjacent to their property is to depreciate its value, and testimony of this nature is commonly accepted in condemnation proceedings.

Heretofore, the generally accepted theory has been that reproductive values should be based on the present market value of contiguous property, plus whatever increment experience and available data might indicate as proper to add to bring it up to its actual cost to the company. Subject to any further review of the question by the Court of

Mr. Aldrich. last resort, its recent decision must stand, but this does not preclude testimony as to actual cost. The unfortunate situation is thereby created, however, of making it possible for a company owning a line constructed in recent years to produce and get the benefit of such testimony, while the records of older lines may not be available. Records of land purchases for many of the Southern roads, for example, are said to have been destroyed during the Civil War.

A valuation of these properties, based on market prices of adjoining lands, might and probably would result in great injustice to them. The Court refers to this added increment as one "over all outlays of the carrier and over the values of similar land in the vicinity," and says:

"It is an increment which can not be referred to any known criterion, but must rest on a mere expression of judgment which finds no proper test or standard in the transactions of the business world. It is an increment which in the last analysis must rest on an estimate of the value of the railroad use as compared with other business uses."

Herein, the writer thinks, the Court is again at fault, if it applies the principle to railroad valuations generally. In the important railroad land valuations made by the writer, he has never considered "railroad use" as an element of valuation, nor has he heard that term used in this connection. It is not railroad use, it is not alone value, but it is cost that justifies the use of the added increment in making these appraisals. The latter are not used to cover "hypothetical outlays," as the Court asserts, but are based on sound reasoning born of experience and fortified with enough, if not all, actual cases to justify this conclusion.

Mr. Eaton. J. Shirley Eaton, Esq. (by letter).—Mr. Wilgus' paper is comprehensive and critical, and is probably the most succinct statement of the problem which has been made. Its distinctive value lies in its emphasis on the indirect elements of cost of reproduction, which are the inseparable incidents of any actual work. Amateurish valuation fails at this point: It tends to limit its scope to the inventory of physical things at physical measurements at time of valuation, extending the parts inventoried at arbitrary unit prices. The practical engineer understands the necessity of large allowances for contingencies, for errors of judgment, and for changes of detail in the course of construction. Each section of road built involves its special risks and adjustment to local conditions. From the standpoint of personal experience the writer would reproduce a railroad property, carrying it through all the stages of an actual construction under usual conditions. Not only would he include supervision, accidents, taxes, and administrative expense, but he would make provision for the costs of capital that must be held in suspense during the period of construction, and also for the necessary working capital.

Mr. Eaton.

In assigning the work of valuation by geographical divisions, under consulting expert supervision for right of way, signals, and special construction, the author keeps his controlling factors in co-ordination, and gives due weight to local conditions. In predicating an assumed interest rate of 6% on an allowance composed half of stock and half of bond financing, he ignores the fact that many railroads are financed on bond issues alone.

A distinction between valuations according to the purpose which they are intended to serve, is unfortunate. A "valuation" should always be complete and the same thing, having reference to that entity which is defined by the operating income. The law is properly criticized in its provision for a valuation less depreciation. A railroad, as this paper so well emphasizes, is not an aggregate of parts, but an organism of parts, progressively integrated and evolved into a homogeneous whole to produce an operating income. The physical parts have two factors of efficiency which, as capital, must be maintained unimpaired, namely, what may be called the current efficiency and the life efficiency. Every year of use exhausts a year of the life efficiency, and so far reduces the capital value of the original plant. Income account, through which are made the adjustments to maintain capital unimpaired, must bear the charge of accumulating the offsetting reserves from which this reduction of life efficiencies is restored later. Otherwise, the net earnings are overstated to the extent that they have not made allowance for dissolution of the plant. In theory, a net earning figure can reproduce itself indefinitely out of the existing plant. A plant from which depreciation has been deducted will not permit of the indefinite reproduction of existing earnings, and a valuation based on original cost less depreciation, therefore, does not represent the necessary capital involved for the continuation of operating income.

The author touches lightly on the mooted question of including unearned increment in valuation, although this is the storm center about which most of the controversies will arise. In the same category with unearned increment are those values in the physical property representing donations by the community, state, or nation, and the reinvested surplus out of questionably excessive earnings of earlier years. Nor does he touch on another point sometimes urged—the practice of carrying the unearned increment through income account instead of through profit and loss, and thus establishing a rate of return that shall reflect back on the capitalization permitted, which practice would be distinctly wrong. We are at a time when principles of private property in a simple economic society are being complicated by the intrusion of vast values which are the direct result of social production. The analytic methods of latter-day bookkeeping are tending to

Mr. Eaton. distinguish these values from those created by individual enterprise and effort, and to relate them to the sources from which they spring. The problem of how to make this distinction and how far to carry it, becomes a critical and real issue with railroad property first, only because here are gathered, in orderly array, vast aggregates of property to which formulas are more easily applied than to the miscellaneous array of property held privately. We are not ready to believe that the conditions of railroad investment are so different as to make them an exception in this particular, but the question that is raised first in this connection will doubtless be extended in time to include privately held properties as well as those devoted to public utility.

One general criticism of this paper, which applies to all treatments of this subject, is the author's indisposition to strike at the social principles involved and his inclination to limit the discussion to terms and concrete phases. The law is not an illuminating guide. The principles of valuation are not yet stated or known, and while they will be evolved inductively in the concrete studies which the practical application of the law imposes, nevertheless, it would be advantageous, in discussing the matter, to have a leading thinker like Mr. Wilgus intimate the larger social consequences of the undertaking. With these wider aspects before us, in meeting the miscellaneous questions as they arise, there will be built up, not only a practical plan of valuing railroads, but a body of experience out of which will emerge a restatement and a more specific definition of property.

Mr. Howard. C. P. Howard, M. Am. Soc. C. E. (by letter).—In the text of the so-called "Federal Physical Valuation" law, the word "physical" occurs once in connection with classification of property. It also occurs once in a marginal subheading. The law, however, provides for a complete valuation, including "other values, and elements of value, if any," and the "present value" of "all lands, rights-of-way and terminals."

In this connection, the writer desires to call special attention to the subject of land values; to certain important elements which affect such values; to other elements of great importance which affect them from a railway standpoint; and, very briefly, to the question of whether these latter should be considered as "land" or "intangible" values.

A mere statement of facts as to the existence and importance of some of these elements might appear sufficient, and any argument on the subject as an attempt to demonstrate self-evident truths; nevertheless, in view of a recent Court decision, a thorough consideration of the subject would seem to be in order.

Suggested Definition of Value.—What is the value of a piece of property? The following definition is suggested: "The value or market value of a property is its greatest actual value for any lawful purpose for which it may be used and for which there is a demand."

A piece of ground may have no value for industrial or agricultural purposes, but it may have a high value as a residential site. Another tract may be valuable as a site for a wharf, railway terminal, or something else. Its highest value governs; or, if it has value for more than one purpose and can be used simultaneously for both, the sum of the values will govern—for instance, fertile farming land underlaid by a coal vein. Mr. Howard.

Cost of Right of Way.—Mr. Wilgus calls attention to the items of "severance and other damages, plottage, etc."

A narrow strip of land laid off across the country without regard to existing boundary lines cannot be purchased at the price obtaining for ordinary farm lands. As a general proposition, nobody would sell such a strip, splitting his farm in two, for anything like the price per acre which would apply to the farm as a whole. Considered as an article of commerce, it costs more to produce it. To the ordinary price for land must be added the depreciation in value of the remaining land, due to separation of parts and other damages. The Courts recognize this in provisions for damage to the residue. The law does not allow any general increase of land values to offset "damages to the residue"; if it did, the man with a farm near the railroad, but not touched by it, would receive the full benefit, and have an unfair advantage over his neighbor who would have such increase deducted from his land damages. An increase in price, therefore, is lawful, just, and customary.

When a railroad is needed, and such a strip is judiciously located, the demand for the property is imperative, even at such increased price.

Its increased value is due to its shape, position, continuity, etc., elements quite different and distinct from its original value for farming or other purposes, and having little relation thereto.

Continuity.—The continuity of a railway right of way is undoubtedly a most important element of its value. A right of way along a mountain stream might be extremely valuable for railway purposes if continuous; but if it is blocked by some impassable obstruction at one point, it would have no value whatever. This, of course, is self-evident.

Value for Railway Purposes.—Railroad companies have fought each other "tooth and toe-nail" for gaps and passes through the mountains, and elsewhere. In these cases the value for a lawful purpose and the active demand for same are perfectly evident. Among a number of contests of this sort, which have come under the writer's observation, the following instance may be cited:

Two railroad companies located their lines through a gap in the mountains. A bought the right of way. B claimed prior location and sought to condemn. The lower Court decided for B, and testimony was taken as to the value of the land. An engineer for A, questioned

Mr. Howard. as to its market value, placed it at $25 000, based on value to its owners for the purpose for which they proposed to use it, that is, for the construction of a railway tunnel. Its value for any other purpose would have been a mere trifle. The sequel is interesting. Road A, being deprived of its right of way, went ahead with the construction of a longer tunnel on another line a few hundred feet south of the main gap. Road B completed the tunnel through the main gap. The Superior Court on appeal decided against Road B, and Road A then had two tunnels.

As a matter of fact, it is perfectly evident that the value of land for railroad purposes is a distinct and important element of value. One line may be worth as much or more than another line which cost considerably more to build, its greater value in excess of cost being altogether due to its more favorable location, that is, the greater value of its land for railway purposes. This does not necessarily imply a difference in engineering skill, the first line having first choice in the selection of its route.

Existing railroads in many parts of the country occupy natural or strategic routes which, from the shape of the land and the general configuration of its slopes, are especially adapted to railroad purposes. At present, these routes are of great value, and are likely to become more so in the future.

The importance of passes and defiles in the mountains is well known to engineers; for instance, the New River Gorge, occupied by the Chesapeake and Ohio Railway; the Ohio River below Pittsburgh; the Allegheny, Monongahela, and Youghiogheny Rivers at and above Pittsburgh; and the Susquehanna above and below Harrisburg.

Let any one spread out the sheets of the U. S. Topographical Survey from Pennsylvania to Georgia, note the railroads which have recently been built, and study the situation carefully. He will see how difficult, if not impossible, it will be to get another low-grade railroad line from the Ohio River to Chesapeake Bay, or to any point on the Atlantic Coast, below Norfolk, without using the tracks of an existing railroad. The Potomac, James, and Roanoke are the only rivers which cut through the Blue Ridge Mountains. On the route from Pittsburgh to the Potomac both banks of the Youghiogheny are occupied; this is also true of the Potomac from Piedmont to Cherry Run, near Hagerstown, Md. Between the Potomac and the Chesapeake and Ohio Railway, are a number of high ranges running northeast and southwest, and lapping past each other like interlocked fingers. From the Chesapeake and Ohio, on New River, southward to the Norfolk and Western Railroad, there are numerous ranges of hills and mountains; and from Roanoke south to Rabun Gap, Georgia, the eastern slope of the Blue Ridge falls off like the roof of a house, with the highest mountains

of the Alleghanies to the west, and still farther west lie the Cumberland Mountains. Mr. Howard.

It is impossible to state how many other railroads would have been built from Pittsburgh east, if there had been a place to put them, or how many east and west lines south of the Potomac; one would have to be familiar with all the various surveys of proposed railroads. The writer knows of one company which attempted to build west, in the territory between the Potomac and the Chesapeake and Ohio Railway; it built a short distance and stopped.

The value of ground for railway purposes, or its location value, is well illustrated in the case of terminals in a large city. If the business is sufficient to justify the construction into the city of a new line (B) at a cost of $10 000 000, then, as a matter of fact, the value of the old line (A) entering the city from the same direction and giving the same facilities, would be not less than $10 000 000, even though the cost of reconstructing it on its present location should be estimated at one-half or one-third that amount.

It may be assumed that the old line, having first choice of location, cost less as to physical features of construction, including grading, bridges, etc., that its land cost less, and that at present it would cost less, if valued on the basis of adjacent property without improvements. The new line, however, has to buy property with improvements; then tear them down, and build its own structures. Stated in another way, the value of an existing line is evidently not less than the cost of its reproduction on a new right of way, when sufficient demand exists to justify the construction of an additional line; and as no one will invest without expectation of increase, to this value should be added a reasonable percentage for profit.

When the business of the route will support only one road, any special value due to its advantageous location is not so apparent. But if the business is increasing toward the time when it may no longer be accommodated by the increased number of tracks of the existing road (and it is only a question of time when a second and more expensive line will be required), then the value of the location of the existing road, or of its lands, for railway purposes, may be said to be likewise increasing.

Credit for Location Value.—It has generally been conceded that the owner of property is entitled to its value for any lawful use, such as farming, building, etc. It is not the writer's purpose to suggest who should be credited with the special value of land for railroad purposes—the State or the railroad—but rather to emphasize the fact that this value exists.

How to Estimate the Value of a Location.—Railroad companies, if left to themselves, might settle the value of their lines, including that of location (or that of their lands for railway purposes), by the natural

Mr. Howard. process of competition, provided they did not combine; but if the Government decides to make a complete valuation of railroads for purposes of rate-making, it must consider the various elements which would fix the value according to natural laws of supply and demand, such as the cost of construction, number of available routes, and number of roads, tracks, etc., necessary to handle the business.

If it decides to give a railroad company the credit (or, in some cases, perhaps, the debit) of the value of its location, or the adaptability of its land for railroad purposes, how may such value be determined? This is a difficult problem, yet railroad companies have had to solve it in the past, and, if left to themselves, will have to do so in the future. It takes investigation, time, and money. To consider it as an "intangible" rather than a land value makes the problem no easier, if an attempt is made to ascertain its amount in dollars and cents. It must be remembered also that railroad companies themselves have not asked for this investigation.

The process of determining the value of a location, as practised by railroad companies, is simple enough in a way; but it is expensive and tedious. A company desiring to build through a certain territory and finding the natural route occupied by another road, makes careful surveys and estimates of the cost of building an alternate line. If it costs too much, an endeavor is made to secure trackage rights over the existing line. If it is found necessary to build the new line, then, other things being equal, the excess cost of the new line over the old, actual or computed, may be taken as the value of the location of the old line, or the excess value of its land for railway purposes.

"Location," "Land" or "Intangible" Values.—There are certain cases where the cost of reproduction on a new right of way would seem to be a logical method of determining the value of land for railway purposes—in other words, the cost of reproducing the right of way; there are other cases where this method might be used as a check or side light. It probably makes no difference whether it is considered as "physical," "tangible," or "intangible," provided all existing information is used and every effort made to determine its true or probable value.

Mr. Brinkley. M. H. Brinkley, Assoc. M. Am. Soc. C. E. (by letter).—While the general principles enunciated by the author are interesting, and the paper is a valuable contribution on the subject of valuation, the writer desires to take issue with some of Mr. Wilgus' conclusions.

Since the paper was published, the decision of the U. S. Supreme Court has been made public, and its conclusions have been very far-reaching in regard to the value to be considered for rate-making purposes. It clearly sets forth that rates should be charged on reproduction value less depreciation, or what might be called depreciated reproduction value. A quotation in part is as follows: "When an estimate

Mr. Brinkley.

of value is made on the basis of reproduction new, the extent of existing depreciation should be shown and deducted." As the significance of the case was the question of rates, there is no doubt of the consequence of the decision that rates should be based on depreciated reproduction value.

In the following discussion depreciated reproduction value will be called present value.

After a railway is built, renewals do not take place at once, but additions and betterments may be made, the cost of which should be charged to capital account. Starting with the property new, there will be a gradual depreciation, based on the rate of depreciation of the different elements of the property. When it is necessary to renew the items of shortest life, allowance must be made for the expense of replacements.

Assume that from the beginning of operation of the railway, the earnings have been sufficient to pay interest on the investment and create an accrued depreciation fund, which, at the end of each year, is equal to the depreciation below reproduction value. If, however, no fund has actually been created, then before renewals start, the net income is larger than in later years by an amount equal to the average annual renewals of the later period. Advantage may be taken of this by paying larger dividends to stockholders, or the amount may be placed in additions and betterments. The latter is frequently done, for often on railways recently built a large number of improvements take place. In either case, the stockholders gain, and there is what amounts to a repayment of capital invested.

For a property which has never made payments into a depreciation fund, the yearly replacements must come out of earnings. Assume that the railway is composed of a large number of elements of different life, such that after a certain age is reached, the present value remains constantly at the same percentage of reproduction value, due to the fact that replacements are the same in amount each year. This is not a special case, as a large amount of railway mileage approaches this condition very closely. If the property is allowed to earn interest on present value, and the cost of the annual replacement is provided for, the rates charged to the public will be the same as if a depreciation fund had been established at the beginning, being kept approximately equal to the total depreciation and earnings continually allowed on reproduction value. In this argument, it is assumed that the rate of interest on the depreciation fund is the same as that allowed on reproduction and present values. The proof of the above proposition is as follows:

Let i = rate of interest allowed on reproduction or present values;
a = rate of interest on depreciation fund;
R = reproduction value;

Mr. Brinkley.

$P =$ present value;

$N =$ annuity required for contribution to a depreciation fund established at the birth of the property, which fund at the end of a certain period will remain equal to the depreciation below reproduction value;

$D =$ value of the depreciation fund;

and $A =$ cost of annual replacements.

Then in the case where earnings had always been allowed on reproduction value and a depreciation fund provided, which after a certain age remains equal to the total depreciation, interest on the reproduction value plus the amount of the annuity must be provided by net earnings, or $iR + N$. As the property is assumed to have reached an age when the annual replacements paid for out of the fund are constant, as well as the depreciation fund, it follows that $aD + N = A$, or $N = A - aD$. Substituting for N its value, the net earnings must amount to $iR + A - aD$. But $R - D = P$, and if $i = a$, the amount to be provided by net earnings becomes $iP + A$. This proves the proposition, as the same amount emerges, which it is contended should be allowed for net earnings where no depreciation fund has been provided. It seems to be clear from the foregoing that if earnings are allowed on the present value, together with a surplus for annual replacements, the property is on the same footing with one which has established a depreciation fund by annuities and is allowed earnings on reproduction value.

If no depreciation fund has been established, it should be assumed that the earnings, which should have contributed to such a fund, have been spent in extra dividends to stockholders or used in additions and betterments, in either of which cases the result is that of a repayment of capital. It is accomplished in the former case by direct repayment and in the latter by increasing the reproduction value of the property without any capital outlay. Besides, the apparent loss in value of the property is very much reduced on any railway more than a few years old by the unearned increment of right-of-way values. The term, right of way, as used, includes real estate and terminal lands. The market value of such land is usually more than the amount originally paid for it, and, in the case of the earlier railways, many times more. With the value of the right of way equal to 20% of the total value, it is easily apparent that, in the case of the earlier railways, the unearned increment of right-of-way values might amount to more than 15% of the value of the property. This, with the appreciation of grading, would be sufficient to take care of the difference between reproduction and present values. There may be some railways of light traffic on which excess earnings in their early life and increase of right-of-way and terminal land values have not been sufficient to balance the de-

Mr. Brinkley.

preciation. In such a case, the stockholders have simply made a poor investment.

If provision is made by the railway company for replacements by a replacement fund of such an amount that it will be just wiped out in the years of heaviest replacements, then it would be equitable to allow the company net earnings sufficient for interest on the present value plus interest on the amount of the fund plus an annuity for the replacement fund. The same result would be achieved by allowing net earnings sufficient for interest on the present value, plus an annual payment into the replacement fund, no interest being allowed to accumulate in the replacement fund, being given to the stockholders instead for the use of their capital in the fund. As the sum of the present value and the amount of the fund will always approximate a constant value, the rates paid by the public should be the same general average through a group of years as if calculated on the basis of present value alone. Also, considering the fund as a part of the capital, no additions to capital account need be made for replacements as their cost will be taken out of the fund.

Depreciation is not a wastage of capital if its capital value is repaid, but, as far as the property is concerned, there is a diminution of value. If depreciation is a liability of the stockholders, earnings should only be allowed on the present value, for, if earnings are allowed on reproduction value, depreciation then becomes a liability of the rate-payers.

If earnings are allowed on reproduction value, and normal depreciation is treated as an element in the cost of operation that is covered by the rate, then, if no depreciation fund has been created, rates must be increased as depreciation takes place and replacements increase, since the reproduction value remains the same.

If there is no depreciation fund, and earnings are allowed on the reproduction value, then this becomes the selling value, as the latter is the capitalized value of the income. It has been agreed by the author, however, that the selling value or the capital invested by the purchaser should be based on the present value. It follows that earnings should be based on the present value instead of the reproduction value.

For property which has been allowed to deteriorate below the normal present value, it becomes a liability of the stockholders to place the structures in fair condition to the extent of the difference between the deteriorated value and the normal present value. In this case the stockholders should be penalized by a reduction of interest on investment sufficient to authorize this difference in values in a convenient length of time. During this time, the replacements necessary to bring the property up to normal condition, would be made. Earnings, insufficient in the past to take care of replacements, would be mitigating circumstances.

Mr. Brinkley.

The decision of the U. S. Supreme Court in the "Minnesota Rate Case" also covers thoroughly the question of right-of-way values. A quotation in part is as follows:

"The company would certainly have no ground of complaint if it were allowed a value for these lands equal to the fair average market value of similar land in the vicinity, without additions by the use of multipliers, or otherwise, to cover hypothetical outlays. The allowances made for a conjectural cost of acquisition and consequential damages must be disapproved; and in this view we also think it was an error to add to the amount taken as the present value of the lands the further sums calculated on that value, which were embraced in the items of 'engineering, superintendence, legal expenses,' 'contingencies,' and 'interest during construction'."

This decision seems to be fair, both to the railways and to the rate-payers. The right-of-way values for the older railways will be much enhanced over the original cost, and it is not probable that the newer lines will suffer any hardship. The normal increase in land values, consisting of yards, terminals, and right of way, after a railway is built, is usually sufficient to provide for the extra cost of right of way over the market value at the time of construction. Some actual data, comparing original cost with present market value for land values of a complete railway system, would be interesting. However, it should be unnecessary to consider this question if we neglect original cost and consider only reproduction value. The present values of adjoining land have been created on account of the existence of the railway itself, and if the railway was to be built at the present time, the present land values would certainly not obtain. The only exception would be in case another railway existed in the same vicinity, which fact would also have influence in creating land values; but in any town certain land increases in value when another railway is built. Nothing can be known of what the land values would be if the railway did not exist. It seems to be expedient as well as good judgment under the circumstances to allow full market value and no more. The only other alternative is to give some consideration to original cost in the fixing of rates. A percentage for contingencies and interest during construction is evidently superfluous, as it has nothing to do with the present market value of the land.

The writer agrees that the ordinary method of calculating interest during construction is unfair to the company. By this method one-half of the total interest allowance for the time of construction is taken; two-thirds or three-fourths would probably be more nearly correct. If this is done, however, care should be taken that a too liberal allowance for time of construction is not made.

The author's views on depreciation are illuminating, especially on the subject of rails. In addition, it would be well to state that rail

breakage should also be considered, and available statistics on this subject for each railway studied. Mr. Brinkley.

It seems to the writer that depreciation in general should be handled only by an expert. The chiefs of ordinary field parties have not the experience and ability to judge accurately of the condition of structures, and the variations in their opinions are too great. In order to obtain the depreciated value, all structures should be examined by an expert and their condition noted. When the inspection is made, he should have the age of the structure, if such information is in existence. The percentage depreciation can be more intelligently noted if the age is known.

In view of this discussion, conclusions indicate that the recent Supreme Court decision in the Minnesota Rate Case, in regard to the basis for the valuation of railroads, is fair both to the railway companies and to the rate-payers. From the arguments and facts it does not seem possible that any other basis for rates than that of present value with right of way included at market value of adjoining lands, could be made without gross injustice.

Albin G. Nicolaysen, Assoc. M. Am. Soc. C. E. (by letter).—The valuation of common carriers to be made by the Interstate Commerce Commission promises to be of such great importance both to the public and the railroads, and opinions as to the proper principles to be followed vary so greatly, that Mr. Wilgus' paper is most timely. Mr. Nicolaysen.

The author has given a clear presentation of his views, and the force of many of the arguments is admitted, but to the writer it seems that the railroads have generally received a little more than the benefit of the doubt. Thus it seems proper enough that some allowance should be made for solidification of embankments, but to advocate that such allowance shall equal the estimated cost of compacting the embankment as an earthern dam would be compacted at the time of its construction, does seem to be rather arbitrary. It is also certain that the surfaces of cuts become seasoned in time, so that the trouble from slides and filling of ditches is materially less in an old than in a new cut, and that the appreciation of the cuts may bear a close relation to the cost of maintaining the slopes from the time of construction until they become fairly stable; but the appreciation of the cuts is somewhat less, and not equal to the cost of maintaining them during the period of settlement, as some cleaning of ditches will always be required. However, where the difference between the two values is small, it seems to the writer to be reasonable and fair to give the railroads the benefit of the doubt, taking into account the fact that, in some cases, valuation for rate-making purposes may work hardship to innocent investors. The author, however, appears to claim that even an additional allowance, equal to the cost of establishing vegetation by artificial means, should

Mr. Nicolaysen.

be made where the cuts have become covered with vegetation which protects the surface. This claim seems clearly against the fundamental principle that physical value is determined as the cost of reproducing the property in its present condition, under the assumption that the natural topographical conditions along the line are as they were at the time when the road was built, while, in other respects, the conditions are taken as they exist to-day; under this theory Nature may logically be assumed to re-establish vegetation in places where it has established such vegetation in the past.

It appears to the writer that most appraisers would make some allowance in the physical value for interest during construction, cost of promotion, banker's commission on securities (but not discount on bonds), contingencies, and similar items, so that the difference of opinion regarding these items would be confined mostly to the question of the proper allowance to make for each. This the writer does not consider himself qualified to discuss further than to state that it would seem reasonable to assume that an examination of the books of recently built roads would disclose data from which these items could be estimated quite closely.

There remains one fundamental question on which the writer differs absolutely with the author, namely, whether the proper physical value for rate-making purposes should be determined as the cost of reproduction new, or whether a deduction should be made from this value to cover depreciation.

As long as it is agreed that depreciation shall be included in maintenance, and that the renewals shall be charged as operating expenses, it seems clear that the physical value for rate-making purposes is the cost of reproduction new, less depreciation. To illustrate this contention it may be assumed that a certain road was built as a unit. When new, the physical value equalled the cost of reproduction new, since no depreciation had occurred. After the road had been in service for one year, a certain depreciation took place, but this depreciation was a part of the operating expenses for that year, and may be assumed to have been placed in a special depreciation fund. If this has been done regularly, there will exist at the present time a fund made up of yearly appropriations equal to the depreciation for each year less the cost of renewals made in the period considered, and this fund should equal the depreciation on the road as it exists to-day. The road under consideration is clearly entitled to a return on the cost of reproduction new without any deduction for depreciation, but the depreciation fund may logically be assumed to be invested in such a way as to earn interest on itself, and the net earnings from operation need only be large enough to provide for a return on intangible values, if any, and on the cost of reproduction new, less depreciation.

Mr. Nicolaysen.

It is granted that such a fund is rarely established, but this does not alter the case; it simply means that the stockholders have drawn out of the road more than was really available for dividends, and have thus reduced their investments in the property by an amount equal to the depreciation. As long as the property is kept in good condition, no objection can be made to the withdrawal of money which, in a sense, belongs in a depreciation fund, because the average condition on a well-maintained road of any magnitude differs but little from year to year, and it will never be necessary, or even possible, to renew all of the property during one year.

If maintenance expenses are considered in connection with the return on physical value, it will be still clearer that depreciation should be subtracted from the cost of reproduction new, in order to determine the physical value on which a return may be expected. If this is not done, then two roads, A and B, for which the cost of reproduction is identical, will be entitled to the same return on their physical values, although A may be a fairly new road and in excellent condition, while B may be old and run down. Under such conditions the maintenance expenses, and, for that matter, the operating expenses too, would be far heavier on B than on A, and, as the roads are entitled to earn maintenance and operating expenses in addition to a return on the physical value, the result would be that the poor road, B, would be entitled to far larger earnings than the good road, A, which shows clearly enough that something is wrong with the basic assumptions. In fact, as the writer sees it, there is no doubt but that the physical value should be determined as the cost of reproduction new, less depreciation.

In connection with the question of depreciation, it would seem that average depreciation, rather than actual depreciation, should be used in the majority of cases. If an attempt was made to base the value for rate-making purposes partly on the actual depreciated value of the physical property, it would mean that the task of revising the valuation in order to keep it up to date would be almost impossible on account of the multitude of items involved. In addition, the writer believes that the result obtained by assuming that, say, all the untreated pine ties on a fairly large road had a present value equal to 50% of the value new, would be more nearly correct than that arising from an attempt to estimate the depreciation of each individual tie, although a still closer value might be obtained by estimating the average depreciation, bearing in mind that the normal depreciation would be 50% and the minimum and maximum depreciation, say, respectively, 35 and 65 per cent.

If average depreciation instead of actual depreciation was used to determine the physical value, the result would be a tendency toward stability in rates, field and office work would be greatly reduced, and the task of keeping the valuation up to date would be made practical.

Mr. Nicolaysen.

It is admitted, however, that the actual depreciation of buildings and structures should be determined, not only because it is required by law, but also because it will furnish a guide in establishing average depreciation of different classes of structures and in analyzing maintenance expenses, the writer's belief being that average maintenance expenses must be ascertained as a step necessary to the determination of intangible values, if any.

As, theoretically, abandoned property must be paid for out of the depreciation fund, it is obvious that such property as a spur to a mine which has been worked out, should only be given a nominal value. The same would necessarily apply to stretches of roads having such curvatures and grades as to make it impossible to operate trains economically over them under present conditions, to bridges which are too light to carry present rolling stock, etc. This, however, should be definitely settled and understood, else the natural result would be a postponement of a very large part of desirable improvement work along these lines, pending the completion of the valuation.

To the writer it seems that the value for taxation purposes may differ from that for rate-making purposes, but he is not certain that it would be impossible to distribute the several items of value between physical and intangible values in a way that is logical, and, at the same time, leaves the physical value the same, no matter for what purpose it is intended. If it were possible, this plan would be highly desirable as tending to give the valuations proper standing with the general public. It requires, however, that the method to be used in estimating the intangible values be determined, and it is greatly to be hoped that some member of the Society will present a paper dealing with this subject.

Mr. Molitor.

F. A. MOLITOR, M. AM. SOC. C. E. (by letter).—The thorough and masterly manner in which Mr. Wilgus has covered the subject of the physical valuation of railways has left little room for further discussion. As the writer's professional experience, however, has been confined solely to the building of railroads, a few points which occurred to him in reading this valuable contribution on the pressing subject now before the Interstate Commerce Commission and the railways may be of interest. It should be stated, however, that the writer's experience has been in the commercial or practical field, and not in the political or academic work of valuation for taxation or rate-making purposes; therefore, his views on the general subject may be biased.

Although the purpose of the Federal Act for the physical valuation of railroads is not stated specifically in that Act or elsewhere, nevertheless, it appears to be for one or both of the following purposes: (1) For rate-making or regulation purposes; (2) to ascertain the value of the railroad properties with a view of determining their present

physical appraisement for the ultimate purpose of Government ownership. Mr. Molitor.

If either of these views is true, then the "original cost to date" is a mere bookkeeping task with the evident purpose of checking the results obtained by the engineering method of "cost of reproduction new" and "cost of reproduction less depreciation." The "sale method" may be dismissed from consideration, because, as Mr. Wilgus states, it can be used for taxation purposes only and hence is a State and hardly a Federal question.

Mr. Wilgus has stated the difficulties to be encountered in obtaining the "original cost to date," and an accountant or engineer may well shudder at the task of ascertaining in only the most general way the original cost of some of the earlier railroads, many of which have been rebuilt on entirely different alignment and right of way, the original roadbed having been obliterated by the elements and become a part of the landscape and topography. What possible value can such approximation of the original cost of a railroad, with additions and betterments and improvements added to date, be to the Federal Government? Or what standing will it have in Court? In fact, to what can an engineer consistently testify in the "original cost to date" except only what the books of the railroad company show?

It seems to the writer, therefore, that the only admissible method of valuation is the "cost of reproduction new" or "less depreciation," and he agrees with Mr. Wilgus' theory that the proper valuation for rate-making and regulation purposes is the cost of reproduction new, the depreciation, if any, being taken care of by the owners and stockholders as a liability. On the other hand, if the valuation is for the purpose of taking over and purchasing the railroad, then the depreciation should be considered only to the extent required in each railroad under consideration. It is at this point that the experienced railroad engineer may use his judgment. The writer is acquainted with many roads which are maintained in a first-class manner and would not in all fairness have any deduction for depreciation, because their general condition for the purpose of the public is as good as, if not better than, when it was new, as viewed and appraised in a broad and equitable light. Speaking academically, it is admitted, however, that each and every tie, panel, or track, or other detail of construction, is not new, and, therefore, from a percentage standpoint, is not "100 per cent. new." It is here that the fallacies of theoretical tables, based on the life of a construction detail or unit, and purporting to give its money value for each year of its life, are evident, when the railroad as a whole, or as an operating plant for the public benefit, is being considered.

Another railroad which by inspection shows a physical depreciation to the extent that repairs of roadbed, bridges, and buildings are required, may well have a "less depreciation" deducted from its repro-

Mr. Molitor. duction cost to the extent that the engineer may estimate, not, however, by counting the bad ties, but by estimating carefully what is required to place the road in proper condition in order to handle its particular traffic economically, and here it must be remembered that the traffic of the Pennsylvania Railroad requires a higher standard of roadbed efficiency than a short line in an outlying district with a light traffic density. Is this not an example of one of the "elements" entering into railroad valuation in respect to the "less depreciation" item? And is it not the point of view to be taken by the valuation engineer that he must apply different standards to different railroads? The writer can well imagine the inexperienced man acquainted only with the maintenance-of-way standards of the Pennsylvania Railroad, or other Eastern railway, being detailed to value some Southwestern line. Would he not unconsciously estimate his "depreciation" on an Eastern standard and thereby injure the Southwestern stockholders?

The writer has discussed the depreciation method because, since Mr. Wilgus' paper was published, the U. S. Supreme Court has ruled, in the Minnesota cases, that it must be considered, and although the writer has been of the opinion that it should rule only in roads under bad repair, we are now confronted with it in the valuation of the best roads, and it seems that, in considering depreciation broadly and having always in mind the traffic carried by each, and, in so doing, particularly avoiding formulas, we bring ourselves under the Supreme Court's decision.

Passing to the details of cost of "reproduction new," which must be first determined, regardless of depreciation, it seems to the writer that, in a general way, such cost can be estimated. It will be closer, perhaps, than an estimate of construction cost based on a careful final location, but, nevertheless, it is an estimate which, as far as graduation and masonry are concerned, is not nearly as close as the "final" estimate of the actually constructed roadbed. The masonry cannot always be reached to be measured. The excavations for foundations and classes of material thus encountered cannot be seen, and many like quantities of construction cannot be determined at all in the absence of plans and actual records of construction. On the more recently built railroads these may be found, but, to the writer's knowledge, no such records exist on many miles of lines, the construction staff having been dispensed with before the construction facts were recorded.

Sometimes the classification and overhaul of graduation quantities can only be estimated in the crudest possible manner. The fact that cuts are many years old prevents the most experienced eye from judging the original classification. Loose débris has slid down, covering the original roadbed walls, or weather has changed the character or classification of the visible material, giving hardly a hint of the

classification of graduation originally moved, and no hint at all as to the quantities of classified material. In respect to overhaul, the original method of handling the work should be known. What sort of plant was used, whether scrapers, wagons, or cars. Here, again, the engineer, inexperienced with the locality to which he is detailed, may fall into error by assuming the use of a grading plant inconsistent with, and expensive for, the original work. Mr. Molitor.

The writer has mentioned some of the units of construction which cannot merely be inventoried or measured, but must be estimated, and, in consequence of which, the personal equation will enter into the valuation to a large degree, requiring eternal vigilance and care on the part of the valuation engineers, in order that their estimates may not be overthrown by the Courts on the testimony of the experienced and expert engineers of the railroad companies.

Referring to some units of construction which can be measured, engineers are sometimes confronted with the unit prices to be placed on them. Land values are the most important of these, and the writer is in agreement with Mr. Wilgus' expressions in respect to using a stated multiplier against the normal market value to determine generally the cost to the railroads, which is known to be in excess of other land purchases; he is compelled, however, to change the method, but not his original opinion, by the Supreme Court's ruling in the Minnesota Rate Case, where it decided against the use of a formula or factor for determining the cost of lands. This decision leaves only the alternative of using the normal present market value, but if abundant proof is offered of the actual amounts paid in good faith for land by the railroads, the writer cannot but believe that such costs of land will be admitted.

"Engineering," in the writer's opinion, has generally been estimated too low, and as far as his experience shows, has been varied from 5 to 10% of the cost of the railroad proper, depending on the locality and topography, as well as the speed at which construction progressed. In the case of a physical valuation, the construction must necessarily be assumed to have continued without interruption due to lack of funds or other causes, otherwise a wide door is opened for varied and excessive engineering expenses. It seems equitable, however, to make due allowance for such delays if they occurred during the construction of a particular railroad.

"Contingencies" is an item which, as Mr. Wilgus suggests, must be given due consideration, and is dependent on the individual cases presented in the railroad valuation.

Such minor items as insurance, stationery and printing, can be taken care of by a valuation engineer in no better manner than that suggested by Mr. Wilgus, but "law expenses" is an item that cannot readily be estimated by comparison with the like expenses of other rail-

Mr. Molitor. roads, because these expenses vary with each railroad and with the necessary legal work that was or should be performed in connection with railroad construction. As a general thing, the writer is of the opinion that law expenses have not heretofore been estimated as liberally as the facts and known expenses seem to warrant. Some railroads, through the selection of a contested route, or through contractors' difficulties, have experienced heavy charges for legal services during construction. When a railroad is valued for the cost of reproduction new, is it to be assumed that no legal difficulties of this nature had been encountered? If so, a just and equitable valuation for this item has not been made.

"Interest and Commissions," which cover the interest on the money invested in the railroad property presumably until such time as the railroad is completed, in operation, and becomes self-sustaining, and bankers' and underwriters' commissions, etc., are items susceptible of division of opinion and many interpretations, when placing a valuation on railroad property.

In the writer's opinion, a discount on bonds, as near as it may be determined by the probable credit of the railroad being valued, should unquestionably be allowed for, as it is part of the investing public's risk assumed in purchasing the securities of a new company, and the interest on which, therefore, should be paid for by the shipping public in the shape of the rates based on the total valuation of the railroad property, which should thus include the discount on the bonds. On one hand we have a small road with poor credit, the original construction bonds of which sold, say, at 60%, while on the other hand there is a subsidiary line of the Pennsylvania Railroad, for instance, the bonds of which, issued for construction purposes, would probably bring par to the investing public. In the consideration of the commissions and discount item in the valuation of these two extremes, should not this be taken into consideration to the extent of allowing no discount in the case of the Pennsylvania Railroad and 40% for discount to be added to the valuation to cover the legitimate risk taken by the investor in the small railroad company's bonds. The public thereby will pay a very small fraction of the interest on the 40% increase in valuation, in the shape of railroad rates. The only alternative would be that the public guarantee the interest on the bonds issued by the smaller company, so that by such additional credit they would bring par and a price equal to those issued by the larger railroad with its good credit.

The interest during construction, of course, is more readily obtainable by multiplying the estimated period of construction by the prevailing interest rate and dividing by the average period of time in which all the money was used, which, for practical purposes, has been taken as two, on the theory that the money expended during construction has been regularly distributed over that period, so that the average

Mr. Molitor.

interest is one-half of the total amount. It is quite possible, on the other hand, that the money expended during construction has not been so evenly distributed as to permit of this course.

A case is within the writer's experience where the graduation was comparatively light, heavy expenditures were made for right of way, and the rails and fastenings were shipped in the early stage of construction, with sight drafts against delivery, so that something like 75 or 80% of the cost of construction was expended in the early months. The remainder, consisting of bridges and buildings, was built after the track was laid, resulting in the fact that 25% of the payments were not actually made until 18 months after 75% of the expenditures were made.

It is believed, therefore, that there is a wide latitude in the consideration of the "interest and commission item" in which errors and omissions may enter, to the manifest injustice of the investing public, on the one hand, and the shippers, on the other, if rate-making and regulation is based on the valuation. The writer is aware that some authorities have questioned the allowance of interest and commissions in valuation at all. To those he would suggest that, in the establishment of unit prices for contract work of any character or in any locality, there is contained this very item which is a universal trade condition and must be recognized. The contractor is obliged to borrow money from his bank to carry on his contract work, as his monthly estimates are admittedly not sufficient to carry his investment for plant and like purposes during its earlier stages. He pays the highest rate of interest, and he is reimbursed for these interest payments in the shape of a percentage added in his unit prices. In many cases the contractor is obliged to pay commissions, and this is also reflected or added in his bid of unit prices made to the railroad company. Therefore, if the railroad company reimburses the contractor for interest and commissions, although they are hidden in the unit prices, why should not the railroad have added to its cost in the valuation of its property by the authorities the item of "interest and commission" as a transaction between the railroad and its banker instead of a transaction between the railroad company's contractor and his banker?

The writer is pointing out some of the items that have come under his experience in railroad construction, and have been practical ones, with the view of promoting further discussion on Mr. Wilgus' paper from those members of the Society who have had charge of or have been connected with State railroad valuation in the past, so that a broad light may be thrown on the subject for the benefit of those who are charged with the Federal valuation of railroad properties.

In the valuation of equipment, Mr. Wilgus suggests that each unit need not be viewed personally by the expert appraiser. Nevertheless,

Mr. Molitor. it would appear advisable for the appraiser to inspect as many of the units of equipment as it is physically possible for him to do.

The writer's theory is that equipment, motive power especially, is subject to heavy wear and depreciation not always in the ratio of its age, because one locomotive or car of an equal age and original construction may have performed a greater mileage, or may not have been maintained as well as another, and though he believes that depreciation of the roadbed and structures must be regarded in the general way as a single proposition, he feels that the equipment can, by actual inventory, be valued with the depreciation deducted and obtained in a careful and more exact manner. At the same time, the general overhauling and repairs made to equipment should be given the most careful consideration. Though the life of an engine may be taken at a given number of years, nevertheless, this life may be lengthened by systematic and careful general repairs and overhauling, which, in the case of many railroads, has been done. The past history of equipment is that it becomes obsolete rather than worn out. Its physical life is longer than its economic life, and it is not at all improbable that the latter should be taken into consideration in the value of equipment. That is to say, the unit value of a car of 100 000 lb. capacity is greater than one of 40 000 lb. capacity because of the greater operating efficiency of the former.

The writer is in the heartiest accord with Mr. Wilgus in giving due consideration and valuation to the preliminary organization expenses which are necessary incidents to the construction of any railroad. From the writer's knowledge, there have been instances in which these preliminary organization expenses have legitimately run into an amount equal to 20% of the cost of construction, and he believes that where a railroad company can show proof that such preliminary expenses have existed, they should be allowed in the valuation.

In conclusion, the writer recognizes the legal limitations within which much of the physical valuation of railroads has heretofore been undertaken by several of the States. He believes that though much of the information gained will be of value in the Federal valuation, nevertheless, there are many additional items which may well be taken into consideration by the Interstate Commerce Commission. He refers more particularly to the so-called intangible values. Some of the values that have been called intangible are not, in his opinion, at all intangible, and he will close by mentioning one very tangible item of the value of a railroad, with the hope of adding to the discussion further remarks on the subject.

The profile of a railroad has a tangible value and, therefore, should be considered in the physical valuation of any railroad property.

The economy of the operation of a railroad plant depends on a great many items, the principal ones being fuel, labor, and the profile. Labor

rates are becoming practically uniform throughout the country, but the cost of fuel varies considerably. No item entering into the cost of railroad operation has a greater bearing on it than the profile, and, therefore, why should not the railroad, which, by advantages of location or by the efficiency shown in the location surveys in obtaining a lower grade line than another railroad, have this advantage expressed in the valuation? Mr. Molitor.

The writer has knowledge of two railroads connecting two industrial centers. One of these has a grade line so much lower than the other that the "movement expenses" or cost of conducting transportation is not more than one-half that of the other road, not so wisely or fortunately situated. Should not the road of the lower gradient be given consideration in the valuation over the road of heavier grades? If valued for commercial purposes, the low-grade line would assuredly be valued higher than the railroad of a higher grade, because its net earning capacity is greater.

As the profile of the road is a physical feature, it would seem that a valuation could be placed thereon. The writer is not prepared to say at this time just how, but that some equitable basis could be arrived at for determining the profile value of a railroad is quite certain, and it is hoped that this subject at least will bring forth an answer from Mr. Wilgus.

The physical valuation of railroads now being undertaken by the Federal Government affords a great field for engineers in general, and for members of the American Society of Civil Engineers in particular, and it behooves them to study the problem carefully with the view of obtaining uniform methods and equitable results, and for such study no better text has been offered than the paper by Mr. Wilgus.

Halbert P. Gillette, M. Am. Soc. C. E. (by letter).—Appraisers of railways and other public utilities differ radically on many important principles, such, for example, as to the propriety of using present unit prices or prices that are the weighted average during a term of years. The writer has found that most of these differences of opinion spring from differences in hypotheses as to the political status of public utilities. Analysis discloses two distinct hypotheses, or theories, which, though rarely reduced to words, exist in more or less definite form in the minds of appraisers. These two theories may be called: Mr. Gillette.

1. The Agency Theory;
2. The Competitive Theory.

According to the Agency Theory, every public service company is a public agent authorized to render certain kinds of service, and entitled to be recouped for all reasonable expenditures and costs plus a fair profit.

Mr. Gillette. According to the Competitive Theory, every public service company is authorized to render certain kinds of service, and is entitled to collect what the traffic will bear under more or less competitive conditions.

It is needless, perhaps, to point out that, until recent years, American railways were not subjected to regulation according to the Agency Theory, but were "regulated" by the natural laws of commerce. Gradually, however, the Agency Theory of regulation has been evolving, but has not yet attained general application. We still see the Federal Government attempting to apply the Competitive Theory to railways, by forcing the dissolution of so-called "competing lines"; while, at the same time, the most "progressive" States are attempting to apply the Agency Theory. The Public Service Commission of the State of Washington recently authorized the consolidation of certain telephone companies, and scarcely was the consolidation effected before the Attorney General of the United States began action, under the Sherman law, to "unscramble" the consolidated companies.

Two political theories, therefore, are now struggling for supremacy; and it happens that these two theories vitally affect the principles to be applied in the appraisal of railways and other public utilities.

According to the Agency Theory, the "value" of a public utility property is the reasonable actual investment of capital in the property. This includes the investment in the physical property and the investment in the "residual development cost" (the unrecouped deficit in fair return on the investment).

According to the Competitive Theory (when logically applied), the value of the property is the cost of its reproduction at present prices, minus the capitalized difference in annual cost of production with the existing plant and with the most modern plant which would give the same service, plus the capitalized value of the profits derivable from the plant during the remainder of the company's franchise or charter. Briefly stated, this "value" is depreciated value plus franchise or going concern value.

Although there is a large element of injustice in suddenly dropping the Competitive Theory—a theory under which railways have so long operated and under which so many stockholders have invested—the recent history of public regulation makes it quite clear that the Agency Theory is destined to be adopted. In the transition period, however, we shall have a mixture of the two theories—a sort of compromise theory.

The State which has gone furthest toward the adoption of the Agency Theory is Wisconsin. We find the Wisconsin Commission, for example, including the "going value" or development cost (equal to the residual deficit in fair return) as a part of the total "value" for

rate-making purposes. Also, it refuses to allow the cost of pavement laid over water pipes, unless the water company itself has paid for the pavement. Likewise, it averages unit prices over a term of years, and, where construction has been piecemeal, it uses piecemeal costs. Each of these four rulings is directly in accord with the Agency Theory, and directly opposed to rulings by some Commissions and Courts in other States where the Competitive Theory may be said to prevail. Mr. Gillette.

Mr. Wilgus gives powerful reasons favoring the use of cost of reproduction new as the "value" for rate-making purposes. The recent decision of the U. S. Supreme Court in the Minnesota Rate Case is adverse to this contention. The Court rules that depreciated value must be taken as the "value" for rate-making. Unfortunately, the railways involved in the Minnesota Rate Case presented their side so poorly that the Court did not have either adequate evidence or well-prepared argument on many vital points. Thus, there was no evidence as to the development cost of the railways. Again, depreciation was calculated by the State's engineer according to the "straight-line formula", and the railways did not have the acumen to put "the boot on the other foot" by demanding that an annual depreciation fund be calculated on the same basis. Had this been done, it would have been shown to the Court that the current maintenance expenditures were not sufficient to cover both the repairs of parts and the depreciation of entire plant units. Several other important errors were made by the railways in presenting their case, but these two are mentioned merely to indicate that the precedents established in the Minnesota Rate Case should not be taken as final by any means.

The author is entirely right in saying that depreciated value is not a rational basis for rate-making. Under the Agency Theory, a new public utility company starting to-day would be entitled to a fair return on its actual investment, and it would lead to "confusion worse confounded" were a part of that investment "written off" each year because of depreciation. The thing could be done, but no useful purpose would be served by doing it, while, on the contrary, rates of charge for service would fluctuate with an ever-changing depreciated value. There is a good deal of "horse-sense" in the illustration used by an attorney who argued that the price of milk is not a function of the age of the cow, growing less as the cow grows older, until it would be almost given away in the latter days of the cow's life. What the provident owner of a cow does is to charge a price for milk which will give a fair return on the investment (not on the depreciated value) plus enough to cover "operating expenses", including depreciation. Should the cow be purchased by another dairyman, it is true that he would pay for it on a depreciated basis, but the depreciated value would be such that, during the remainder of its life, the same

Mr. Gillette. price for milk would yield both a fair return on the lower price paid for the cow and enough to cover "operating expenses", including the remaining depreciation.

The Agency Theory applied to new railways will unquestionably lead to the use of the actual cost of the property as the rate-making basis, for it is not rational to burden the present, in order to relieve the future, patrons of the road, as would occur if depreciation were "written off" and rates were based on depreciated value. But what shall be said of the application of the Agency Theory to old railways which now, for the first time, come under the actual application of this theory? The writer believes that justice demands the most liberal treatment of public utilities, particularly in this transition period. Certainly, it is not liberal to appraise for rate-making any of the property of a railway at less than its cost new. Moreover, to use the depreciated value for old roads would be to apply a policy that would not be applied to new roads, in rate-making. Of course, it may be contended that the owners may thus be paid twice for accrued depreciation, because they have already taken out in dividends enough to yield a fair return plus enough to cover the accrued depreciation. Even were this so, we should not lose sight of the fact that the present owners were not the original owners; and they had no way of foreseeing the advent of this new theory—the Agency Theory. The writer, however, is confident that a careful analysis of the ledgers of all railway companies, as far back as accounting records are obtainable, will disclose that the residual development cost is sufficient to wipe out all accrued depreciation, and more too. Development cost is not, as commonly supposed, a matter of ancient history; for the truth is that almost every extension of a railway involves development cost (deficit in fair return). No sooner has the average railway "nosed out" of its development period than it makes an addition or improvement which plunges it into another development period, the surplus from the old investment being swallowed by the deficits of the new. Can there be any doubt, for example, that the great, new terminal of the Pennsylvania Railroad, in New York City, is a cause of deficit at present, in so far as that terminal is concerned?

This matter of development cost leads to another phase of the subject of appraisals. Mr. Wilgus says:

"With rare exceptions, it is extremely doubtful that the books and records of the railroads of the United States will be found to be dependable for the purpose of ascertaining present-day fair values. Only in recent years have cost accounts been kept in a uniform and complete manner, and even then the almost universal tendency has been to understate charges to construction, and to additions and betterments."

The writer does not agree with the author, either that correct railway accounting is of recent origin or that the records are not depend-

able as a guide for appraisal purposes. He recognizes that old records are not always complete, but the gaps are surprisingly few in most cases, and not difficult to fill by estimates which cannot possibly alter the totals by very appreciable amounts. The railways of America would err seriously were they not to conduct the most thorough analysis of all their old records. Their first great error would be their failure to demonstrate what their development costs have been. Development cost (that is, deficit in fair return) cannot be proved satisfactorily except from accounting records. Their second great error would occur through failure to find all the elements of physical value created by necessary expenditures which cannot be seen with the eye. This, it may be said, can be covered by adequate allowance for "contingencies"; but, who knows what is adequate? The writer had occasion to appraise a large property which had been previously appraised by an engineer who had added 10% for contingencies, but whose appraisal still fell short, by 20%, of the actual cost of the property. Failure to hunt for and analyze the accounting records was at the bottom of this serious underestimate. The company was a consolidation of more than a dozen smaller companies, and the earliest accounting records were nearly 25 years old. Were the earliest of these records valueless in a present-day appraisal? Some, it is true, were of minor worth, but they covered minor elements of value. Nearly all the records served to throw light on elements of present-day value which, otherwise, would not have been discovered.

Mr. Gillette.

In this connection, it may be added that the maintenance records should also be analyzed, for it is true, as the author says, that perfectly correct accounting has not invariably existed. Minor expenditures, which should have been charged to property account, have not infrequently been charged to maintenance, and the sum of these minor expenditures thus charged may be quite considerable. Conversely, abandoned or superseded property has not always been charged to maintenance, but occasionally has remained in the property account. This is particularly true of abandoned railway roadbed. A careful analysis of the construction and maintenance accounts, guided by the appraisal of physical property now visible, will result invariably in the discovery of values which otherwise would not appear in the appraisal. Not only will additional quantities be thus found, but larger unit prices will be deduced; and in this connection it may be well to add that unit prices should not be those obtained under rather favorable conditions, but under average conditions. A favorable condition, for example, would be "summer work". Winter work is an unfavorable condition, but one which is often imperative in railway construction, in order to keep down the interest and development cost. The history of the Northern Pacific extension to the Pacific Coast shows that at times

Mr. Gillette. almost as many men were engaged in shoveling snow as in shoveling earth. It was such conditions as this, coupled with other unforeseen difficulties, and followed by a much greater development cost (deficit in fair return) than was anticipated, which threw the Northern Pacific into bankruptcy not long after its completion to the Pacific Coast.

In recent appraisals made by the writer, it has been his practice to allow 5% for contingencies where the construction ledgers were all available, but where the original records of physical quantities were rather meager. If both ledgers and engineering records of quantities are fairly complete, the allowance for contingencies may safely be eliminated, provided liberal unit prices are used. It should be remembered that a contingency factor is automatically introduced whenever liberal prices are adopted.

Regarding brokerage fee, the writer agrees with the author in its inclusion as a part of the cost; but, of course, the same end may be obtained if the rate of fair return is made high enough to allow for all the discount on bonds, including the brokerage fee. This last view was that taken by the Washington Railroad Commission when the writer was its chief engineer, and it is the view now taken by most of the State commissions.

Interest during construction should certainly be calculated on all land as well as on other physical property. The writer was not in direct charge of the appraisal of the land for the Washington Railroad Commission, and, therefore, did not calculate any of the overhead charges on it. In fact, no overhead charges on the land appear in the final land values fixed by the Commission. It is possible that overhead costs on land were omitted, or else that they were included in the "right-of-way multiples". The writer calls attention to this particular case for two reasons: First, because he believes it to be a mistake not to put the entire appraisal of all railway property under the direction of the engineer in charge. Second, because the writer's total overhead charges on the plant, exclusive of land, have often been divided by the sum total of plant, inclusive of land, giving an erroneous result when taken to indicate the total percentage allowed by him for overhead charges. The author of one book on appraisals and many writers of articles have unwittingly been led into this error.

This is not the only kind of error which has been committed by writers in comparing the percentages for overhead costs allowed by different appraisers. For example, one appraiser may estimate 5% for business management, and another would include this item in the unit price and, therefore, not show business management as a separate overhead cost. Many railway construction contracts have been entered into with a managerial contractor on a "cost plus 5%" basis. The recorded contract prices are then sub-contract prices. An appraiser

Mr. Gillette.

may either use these sub-contract prices and subsequently add 5% as a business management item among other overhead costs, or he may increase all the sub-contract prices by 5%, calling them contract prices, and show nothing separately for this business management. One needs to know the method used by an appraiser in arriving at his unit prices before one can interpret correctly his estimates of overhead costs. Not a few appraisers "bury" many of the overhead costs, leaving but a part to appear specifically as such in the final summary. The present practice of the writer is to show all overhead costs separately. They commonly total fully 25% of the cost of the "unloaded" property.

As previously stated, the Washington Railroad Commission restricted its engineer to a consideration of plant value only, exclusive of land. Hence, working cash capital, brokerage fee, and development cost did not appear among the items estimated by the writer. The Commission listened to more or less testimony by the railways on "going concern value", etc., but announced its conclusions without stating any definite theory as to non-physical values. This failure to delegate to its engineer the study of all elements of value is one which the writer regrets exceedingly. The railways were equally mistaken in thinking that a determination of non-physical value was not an engineering problem; consequently, they did not make a satisfactory presentation of their case as to non-physical values. In all subsequent appraisals, the writer has insisted on having full charge of the entire appraisal, including determination of development cost, land values, analysis of accounting records, etc. Some one with technical training should always be placed in full control of any appraisal which is to be used as a basis for rate-making. If an example were needed to illustrate this point, it could be found in the Minnesota Rate Case, where the railway companies erred so seriously through not having the entire technical part of their case directed by engineers. The natural tendency of a railway company is to ask each department to prepare its part of the data, and the result is a more or less confused mass of facts—often facts which conflict because of their incompleteness or because of the incorrect use of terms. In the Minnesota Rate Case, both "right-of-way multiples" and "overhead charges" on land were thrown out by the U. S. Supreme Court. The inconsistent use of words and lack of proper definitions of terms account as much as anything for this erroneous ruling, for the Court was attempting to use symbols which it did not fully understand, and did not understand because they were not clearly and properly defined by any witness.

It would seem that attorneys would always see to it that at least the definitions of technical terms would be precise, and that witnesses would adhere to such definitions; but attorneys themselves are often lost when it comes to the use of engineering and other technical lan-

Mr. Gillette. guage; so that, if a technical rate case is to be presented properly to a commission or a Court, it should be presented by engineers and by those who have been taught by engineers to use technical terms properly and always with the same significance.

When railway appraisals first came to be used as a basis for rate regulation, all, except engineers, regarded an appraisal as being somewhat analogous to a merchant's inventory of stock on hand—a very simple, though often laborious, process. Gradually it has become evident, even to non-technical men, that an appraisal for rate-making purposes is exceedingly technical and complex. When it is realized, also, that rate-making based on cost is even more technical than appraising a property, we shall have an end to the "hot air" testimony of rate experts who are experts only in fixing rates "as high as the traffic will bear."

Appraisal and rate engineering has already become one of the many branches of engineering. The engineering specialist in this line should be primarily a logician, skilled in the use of language and in the science of reasoning. He should be thoroughly acquainted with the general principles of economics and particularly with the principles of engineering economics. He should be well informed as to the decisions of State and Federal rate-regulating commissions, as well as Court decisions bearing on valuations and rates. He should be personally acquainted with specialists in many lines, so that he may select men competent to give any desired information. He should be thoroughly grounded, not only in the principles of accounting, but in the mechanical details of public utility accounting. He should be an incessant student of the new phases of his specialty and of unit costs of construction and operation. Executive ability is also essential to him, but need not be of as high an order as that required of one who is constantly directing large enterprises. It is needless, perhaps, to add that his character should be such that he would make an impartial judge. Obviously, no man can attain the ideal in this, or in any other, branch of engineering; but, at least, those who employ appraisal and rate engineers should aim to secure men who are idealists rather than opportunists, for this is not a profession where mere advocates will survive.

Mr. Willoughby. J. E. Willoughby, M. Am. Soc. C. E. (by letter).—The writer is in accord with Mr. Wilgus in his conclusion "that the cost of reproduction new appears to be the only measure of physical value that places all railroads on the same plane, and the only one that provides for the inclusion of every element of cost that enters into the creation of a going railroad," but cannot agree that he has taken the correct view of depreciation.

It is true that in a well-maintained railroad the accrued depreciation in track and structures does not lessen its capacity as a carrier to perform the work for which it was created, nevertheless, the monetary value of a railroad with track and structures representing 55% of the service that would be obtained from a railroad with all its parts new (all other conditions being unchanged), is less by the amount of the depreciation. Of the capital originally placed in the track and structures, 45% has been consumed. The replacement of this capital can be effected practically only by the creation of a depreciation accounting with a credit which at all times will be equal to the accrued depreciation. The depreciation fund is properly accumulated from year to year as an operating expense, and is to be regarded as an item of value (just as working capital is) which enters into the total value of the railway property whether that value is being ascertained for the purposes of sale or of rate-making. The value of the physical features of any railway property at any time is: Mr. Willoughby.

The total cost of reproduction new, less the accrued depreciation on those parts so affected, plus the accrued appreciation on those parts so affected, plus the amount of the fund provided for the renewal of the parts on which depreciation has accrued.

In many of the existing railways a depreciation fund, if set up now in the accounting, would cause to be shown a profit and loss deficit which would properly reflect itself in a deduction from the market value of the stocks. The meaning would be that, in the past years of the railway's operation, a definite portion of the capital originally put into the track and structures has been consumed instead of being charged out annually as an operating expense. Certainly, the same arguments which caused a depreciation accounting to be set up for rolling stock, apply to the track and structures.

It has been advocated that inasmuch as the annual repairs and renewals, a part of the annual operating expenses, are sufficient to replace the amount of the annual depreciation, a depreciation accounting is useless. Such a view ignores the capital consumed during the early years of the railroad's operation, when the annual repairs and renewals did not replace the annual depreciation.

There is unanimity of opinion that the accrued appreciation in the roadway and right of way should be taken into consideration in fixing the cost of reproduction new. When that is done, it is proper to consider also the depreciation.

The writer believes that obsolescence should be considered as a form of depreciation, because depreciation, in the sense used in connection with the re-valuation work, covers any deterioration of the part affected from any cause by which that part has a less capacity to perform the work for which it was created.

Mr. Whinery. S. WHINERY, M. AM. SOC. C. E. (by letter).—The author refers to the widely different opinions and practices of engineers, appraisers, and the Courts in the valuation of land used for right-of-way and other railroad purposes. Such differences are doubtless largely due to the fact that the purpose for which an appraisal is made controls the point of view to a greater extent than in any other class of railroad property. This fact seems not to have been generally recognized and given proper weight in appraisals and in discussions of the subject, particularly by the public.

The importance of the fact that the purpose for which an appraisal is made must control the methods and values used, was early impressed on the Commission appointed in 1909 to re-appraise the railroads and canals of the State of New Jersey.

The Joint Resolution under which the work was undertaken, required that the Commission should prepare and report a "true and complete inventory and appraisal of the true value" of the railroad and canal property of the State, and, further, though rather incidentally, stipulated that the valuation "shall be in a form available for the purpose of taxation under existing laws".

In their first (progress) report, the Commissioners stated:

"It is not positively stated in the Joint Resolution that the valuation is to be solely for taxation purposes. A true and complete inventory and appraisal of value seems to be called for regardless of the purpose for which the valuation is made. But the term 'True Value' is not definite, since the value of any property varies with the standard of value applied and the point of view from which it is judged. From the very nature of railroad property and the manner in which it is held its market value, in the sense in which that term is applied to other property, is difficult to determine. The commercial value of a railroad is usually determined by its net earnings and the returns made to its owners, quite independent of its cost or of the value of the property it possesses. Frequently there appears to be no close relation between the cost of a railroad and its commercial value. Valuations for the purpose of fixing rates, or for determining proper rental, or terms for joint running operation may also be quite apart from the commercial or the intrinsic value. The value of the franchises and the other intangible property of a railroad may be differently appraised according to the purpose of, or the point of view from which the appraisement is made. Finally, the value of this class of property for taxation purposes may be quite different from any of those named above. It seems, therefore, impracticable to apply any single valuation of the railroad and canal property of the State to more than one specific use, and if this be true, it follows that the purpose of the valuation should be determined upon before an appraisal is made.

"In view of all these conditions, and after a careful consideration of the Joint Resolution, and in view of the necessity of establishing the particular kind of value we are called upon to determine, your Board has thought it best to appraise the various railroad and canal

Mr. Whinery.

properties from the viewpoint of the use of the appraisal mainly for the purposes of taxation."

From the wording of the Resolution, it may fairly be inferred that although the members of the Legislature had in mind the use of the valuation chiefly for purposes of taxation, they were under the impression that the phrase, "a true and complete inventory and appraisal of the true value of railroad property", could be applied to any purpose for which the value of the railroad and canal property of the State might be needed.

There is abundant evidence that the same idea is held by a majority of the public, including members of Legislatures and of Congress. It is important for many reasons that the public mind should be disabused of such erroneous conceptions, and it should be one aim of public discussions of the subject to educate the public on this point.

In fact, there is great need that the public should be educated on the whole subject of the valuation of quasi-public property, and for this reason it would be well that technical discussions of the subject should be sufficiently elementary, and couched in such language that any intelligent citizen could read them understandingly; and that a greater effort should be made to give these discussions as much publicity as possible.

The question of the proper valuation of railroad real estate is complicated and made more difficult by the widely varying elements which enter into the original cost of the property and the conditions under which it was acquired and is held by the railroads. These elements are of such character and of such magnitude that the ordinary standards of fair market price are usually only partly applicable in determining the value of the right of way, either at the time it is acquired or later. Even where the cost of the property to the railroad is ascertainable, it is not always a correct basis of valuation for some of the purposes for which an appraisal may be required.

In discussing the subject, it is the purpose of the writer to deal chiefly with broad general principles, but to consider these somewhat more in detail than has been usual, and to review the various elements of cost and value that enter into an appraisal, for any specific purpose, of right-of-way land. It seems to be necessary, in the interest of clear statement and argument, to recount facts and principles which are neither new nor novel, and the discussion, therefore, may be somewhat tedious to the reader. The writer will attempt to deal with the matter from what he conceives to be a sound and reasonable business standpoint, with little reference to statutes and Court decisions, which may vary in different States. In any specific case, the laws and Court rulings controlling in that locality must, of course, be complied with,

Mr. Whinery. but sound principles of justice and equity must be the fundamental basis of all appraisal work.

What will be said refers more particularly to right of way proper, rather than to lands acquired and held by railroads for terminals and other improvements. The status and basis of valuation of these latter may, and usually do, require special consideration and treatment.

Right-of-way land is held by the railroads under one of two forms of tenure: ownership in fee simple, or some form of easement. In the former, absolute title to the property is conveyed to the railroad; in the latter, only certain rights to occupy and use the property for a specified time or purpose are acquired. The distinction is clear enough in theory, but not always in practice. A conveyance in fee simple may contain conditions, as a part of the consideration, which may cause the property to revert to the grantor, or which may be a continual menace to the title to the extent that it amounts to little more than an easement; and an unconditioned, perpetual easement may be equivalent, for practical purposes, to ownership in fee simple. The tenure under which the land is held by the railroad, therefore, is a matter to be given due weight in its appraisal; but, for the purposes of outlining general principles in this discussion, it will be sufficient to consider only right-of-way land owned in fee simple by the railroad.

Into the consideration, or price paid for a typical right of way, however that price may be determined, three principal elements usually enter:

1. The fair market value of the land.
2. Permanent damages to the remaining property from which the right of way is severed.
3. Temporary damages.

To the sum of these items must be added, to find the actual cost to the railroad:

4. Expenses incidental to the acquirement of the property.

Permanent damages are such as permanently impair the value of the property, a part of which is taken, for the uses to which it is, at the time of the transaction or may be in the future, devoted. The cutting of a farm into two parts, separated by a railroad, involving permanent inconvenience, danger, and increased cost of improvements and of operation, interference with drainage, or with satisfactory sub-division, is an illustration of permanent damage. Temporary damages are such as entail the expenditure of money or cause temporary inconvenience and loss, but do not of themselves impair the present or future fair market value of the remaining property. The cost of moving a building located on the right of way to a new site where its value, convenience, and usefulness to the owner

are not decreased, or the cost of removing or rebuilding fences and other improvements, are fair illustrations of temporary damages. Mr. Whinery.

While these elements of market value, permanent and temporary damages, may not be itemized separately in the settlement or award, it is safe to say that they enter into the aggregate consideration paid for nearly every right of way acquired. The necessity for recognizing and distinguishing between them in some appraisals will appear subsequently in this discussion.

The fourth element, incidental expenses incurred in obtaining a right of way through a property, is as truly a part of the actual cost to the railroad as the nominal price paid to the owner. This would seem to be such an obvious fact as to require no argument, and yet it has been denied or ignored in some Court decisions and in a number of appraisals of cost of reproduction. It includes such items as cost of conferences and negotiations, legal services, cost of condemnation proceedings, etc.

The compensation or consideration paid for a right of way is determined either by mutual agreement or by the award of a theoretically disinterested body of men, on the evidence presented, in the judicial procedure known as condemnation. In case of settlement by mutual agreement between the railroad and the owner of the property, the amount of consideration may vary nominally from zero (donation) to any figure which the railroad may be willing to pay and the owner to accept. The compensation thus agreed on, however, cannot always be taken as a just measure of the cost or value of the property transferred. There may be other valid considerations, which may or may not be named in the deed, but, whatever they are, they do not affect the actual value and, generally, not the ultimate cost of the property to the railroad or its appraisal value for some purposes. This is true even where the right of way is donated. If one friend is good enough to donate to another \$1 000 to be used in establishing a new business, and the money is thus used, it becomes, legally and morally, as truly a part of the latter's invested capital as the money supplied by himself. As a matter of fact, however, a donation of right of way is practically almost never a donation except in name. The so-called donor expects to, and usually does, in some way, get value received, and the railroad pays a price, usually in the form of supplying service for a time at a loss, due to the building and operating of its road in advance of the time when the developed business becomes sufficient to yield adequate returns. It may safely be asserted that in such mutual settlement a fair and proper consideration passes, directly or indirectly, between the grantee and grantor, and that the full value or ordinary cost of the donated right of way should be reckoned as a part of the money invested in the road.

Mr. Whinery.

On the other hand, if the railroad agrees or is compelled to pay an exorbitant price for the right of way, it must be assumed, unless fraud or gross misconduct can be shown, that the money so paid represents as truly a part of the legitimate and necessary cost of the road as though it had been expended for rails and cross-ties. This is true whether the sum paid was a reasonable price for the property or included excessive actual or alleged damages, or was consented to by the railroad to avoid delay or litigation. Where the right of way is secured by condemnation, the theory is, and the fact must be assumed, that the compensation awarded was determined by a body of competent and disinterested men after weighing all the facts, and that the sum awarded was fair and just, and is, therefore, a proper charge against the cost of the road and a like credit to its capital account.

An appraisal of the value of the physical property of a railroad may be undertaken for a number of purposes, among which may be named:

1. To ascertain the cost of the railroad for the purpose of determining the reasonableness of its capitalization;
2. To ascertain the value or cost of the railroad property as an element in the determination of proper and reasonable rates;
3. To determine the value of the property preliminary to a prospective purchase or sale of the railroad;
4. To ascertain the value of the railroad property for the purposes of taxation.

Confining the discussion to right of way and real estate, we may consider the principles and practice that should control in an appraisal for each of these purposes, or cases.

Case 1.—Appraisals to Determine the Reasonableness of Capitalization.—The word "capital" is variously defined. Applied to railroads, it is generally understood to mean the amount of outstanding evidences of cost or debt in the form of stock and bonds. The scientific as well as the ordinary and common-sense definition, however, is that capital is the amount of money permanently invested in a business, and the word is used in that sense in this discussion. It is a reasonable proposition that the evidences of indebtedness of an enterprise—stocks and bonds—should not much exceed the amount of money actually invested in the business, which, in the case of a railroad, may be defined as the amount of money expended originally in its organization, financing, construction, and equipment, plus the amounts since expended in additions and betterments, plus a reasonable amount of free money required for conducting the business, commonly called working capital; and the object of an appraisal, with reference to capitalization, is to determine whether such equality exists.

From this point of view, the question of capitalization is essentially one for the accountant rather than the appraiser. Under usual or normal conditions, neither the present reproduction cost nor the market value of the property can be relied on to disclose the amount of capital which has been actually and legitimately invested in the railroad. Thus, it is possible to conceive of two roads which, to-day, are identical in every respect. One of them, however, was built a generation ago and the other quite recently. When the first was built, the prices of construction work and equipment were materially lower than when the second was built, and the capitalization of the latter will necessarily be correspondingly higher. It would be obviously unjust to assume, because their property now inventories the same, that the younger road is over-capitalized. Mr. Whinery.

The real question to be answered is: What amount of money has been, and, therefore, is now, actually invested in the property? In other words, it is a question of cost and not of present value. The principle is here stated in its broadest terms, and certain reservations must be kept in mind. The permanent destruction or abandonment of property, the payment of dividends out of capital or out of earnings necessary to maintain the property in normal condition, and other like practices which are, if not dishonest, violations of sound business principles, may impair the capital, and if found to exist, must be taken into consideration. On the other hand, the retirement of bonds by paying them off, though it may reduce the outstanding evidences of indebtedness, commonly called capitalization, does not decrease the actual capital or money invested in the road.

Unfortunately, correct and adequate accounts of expenditures chargeable to capital account from the beginning are usually not available. Either they are wholly absent for early periods, or are incomplete, or have not been kept in such a way as to distinguish clearly between betterments on the one hand and maintenance and operation on the other, and it is impossible to determine from them the true investment cost. The very common practice of charging extensive betterments to cost of operation or maintenance, which has prevailed to a large extent in the past, is a pertinent illustration of this condition.

In the absence of complete and trustworthy accounts, an appraisal of the property may be resorted to as the best way to ascertain an approximate estimate of the amount of money invested, or, in other words, the reasonable capitalization.

If the principles here laid down are sound, it must be obvious that an appraisal for this purpose should aim to disclose the actual cost of the property and not its present reproductive cost or marketable value. An inventory of existing property is, of course, necessary, but the unit prices applied to determine aggregate value should be those of

Mr. Whinery.

original cost and cost of betterments at the time they were made. Neither depreciation nor appreciation of original values has any proper place in such an appraisal, unless it appears that the capital has been impaired by some of the actions or causes already mentioned.

The depreciation of the property by ordinary causes (excluding those named which obviously impair the capital) does not decrease the amount of money invested, nor does it ordinarily decrease the capacity of the property for rendering service, as long as the property is kept in reasonable operating repair. A locomotive, for instance, may be ten years old, and yet be as capable of efficient and economical service for the work required of it as when it was new. Even when so worn out as to be incapable of satisfactory service, it will be replaced by a new one, which, if purchased at the same price as the old one, will neither increase nor decrease a properly kept capital account. Nor will any depreciated value assigned to it at any time affect the amount of money invested, on which interest and dividend charges must be paid.

On the other hand, any appreciation of the value of a property, by causes other than the actual investment of additional capital, does not affect the capital account. It is a so-called unearned increment which properly belongs in a surplus rather than a capital account. Nor should earning capacity represented by the market price of stocks or bonds be given any weight.

Applying these principles to the appraisal of right of way and real estate, it follows that the object should be to ascertain and use values which represent the actual cost of the property to the railroad. In such an estimate of the value of right of way all the elements which go to make up the total cost, fair market value, permanent and temporary damages, and incidental expenses, should be reckoned and included. Practically, this may ordinarily be accomplished most satisfactorily by applying a properly determined ratio or multiplier to the fair local market value of similar land at the time the property was acquired. Usually, sufficient records of actual cases will be available to establish, with reasonably close approximation, the value of the multiplier to be used. This matter will be considered more at length under Case 4.

Case 2.—An appraisal made for the purpose of establishing or regulating rates should be governed by the same general principles and methods as one made to determine the reasonableness of capitalization. In fact, their ultimate object and uses are substantially the same.

The lowest rates which a railroad may reasonably or legally be required to charge are such as will repay the total cost of the service rendered, including interest charges and a fair return on the money invested, as any lower rates would be confiscatory. Interest and dividends are a part of that total cost, and as they are functions of the capital invested, the latter must be known in order to determine legitimate cost and to frame proper rates.

Mr. Whinery.

This is the only logical theory on which an appraisal of physical property can be called for or utilized as a basis for regulating rates, and, therefore, an appraisal for this purpose should disclose the amount actually invested, as in Case 1. This applies to right of way and real estate as well as to other property.

It is true that enhanced value of real estate may increase the amount of taxes assessed against and collected from the railroad company; but, in the usual method of railroad accounting, taxes paid are treated as an item of expense separate from and independent of interest and dividends, and do not, therefore, affect the capital account.

Case 3.—An appraisal made for the purpose of determining the value of railroad property in a contemplated purchase or sale will necessarily differ in many respects from one made for the purposes named in Cases 1 and 2, and the character of the appraisal will vary with the nature and circumstances of the proposed transaction. When the proposed sale is by mutual agreement between parties equally disposed and free to deal, the appraisal is essentially equivalent to the ordinary invoice of industrial or commercial concerns. In other words, its purpose is, chiefly, to disclose market value. Such transactions are mostly between private parties, do not concern the public, and need not be considered here. But where a Government elects to acquire property by the exercise of its power of eminent domain or other coercive processes, regardless of the owner's desire or willingness to sell, the situation is wholly different. If the owner is to be deprived of his property, he is entitled to full and even liberal compensation therefor. This applies, not only to the naked value of the physical property, but to franchise rights and other intangible values, and to any special physical conditions which may make the property especially remunerative. For from any sound business standpoint, present and prospective earning capacity is more truly a measure of value than the cost of the property or its physical value, and is as much a real asset as physical value. Therefore, the guiding principle in an appraisal of the property should be to ascertain its present and prospective productive value, of which original cost or cost of production will be only one element.

The soundness of these views will hardly be questioned in the case of the property of any private person or corporation whose title to the property is clear, equitable, legal, and untainted by fraud. It does not matter when or how such a sound title was acquired, nor whether the property would be of equal, or in fact, of any, value to the purchaser.

In the case of railroads and other quasi-public corporations, created and existing under governmental permission or franchise, however, the title is clouded by stated or implied reservations embodied in the franchises, and this fact must be taken into consideration.

Mr. Whinery. These franchise reservations, it is true, do not confer any rights to ownership or title. The right and power to expropriate the property of private owners without their consent are derived from a different and wholly independent source—the doctrine of eminent domain, which may be exercised in any case for the public good. The rights and powers of Government derived from franchise grants do not usually extend beyond a certain degree of control or regulation for the public good. It is claimed by the legislative, and affirmed by judicial, authority that the Government may intervene in the operation of a quasi-public corporation to the extent of requiring satisfactory service for reasonable charges; but the question, what are reasonable charges, is still an open one. In fact, it is one which is very difficult to decide, not only in a general way, but as to any particular case. It will be conceded by nearly all fair-minded people that, where the service is inadequate and rates are not only oppressive to the public but yield excessive profits to the owners, it is not only the right but the duty of the Government to intervene and to establish relations between the two which will be fair and just, with due regard to the rights of each. It seems to be widely held that reasonable charges are only such as will repay the cost of the service and yield a fair return on the capital actually invested; and fair return is defined to mean little if any more that the prevailing rate of interest. This theory does not recognize intangible property, such as productive value, and, if enforced, might greatly depreciate any value of the property based on its special earning capacity.

The combination, in the hands of the Government, of the franchise right to control, and the eminent domain power to expropriate, property, unless wisely administered, may be a very dangerous one. If a quasi-public enterprise may be forced to extend its service and reduce its rates to such an extent as to cripple its earning capacity and thus to reduce greatly its commercial value, and the Government may, later, seize or condemn the property at the reduced value created by its own acts, the result may be as truly confiscatory as if physical property were taken without compensation to the owner. It is true that the National Constitution prohibits the taking of private property without due compensation; but it is silent on the question as to what constitutes due compensation. This question must be answered ultimately by the Courts. Thus far it has not been answered conclusively and fully as to the intangible values of quasi-public corporations; and until it shall be so answered, the question of a proper appraisal of such properties for the purpose of an enforced sale cannot be decided definitely. There are hopeful indications that the broad ground may be taken and sustained that productive value, in whatever form it may be found, whether physical or intangible, shall be given proper consideration in such appraisals.

In the present unsettled condition of many questions of detail, it is most important that an appraisal of this character should be thoroughly and intelligently considered by the authority ordering it, and that definite instructions as to the principles which shall control it be given to the appraiser, who must then be wholly governed thereby. Mr. Whinery.

Assuming that the owner is entitled to compensation on the basis of a reasonable regard for the productive value or earning capacity of his property, as well as for its physical value, the general principles outlined apply with special force to the appraisal of right of way.

While a country is new and unimproved, a right of way may have been acquired at a very small cost. Not only was the market value of the land very low, but the conditions were such that both temporary and permanent damages were almost negligible; but, to secure an equally good right of way through the same locality after the lapse of 15 or 20 years, when the country has become thickly settled and costly improvements have been made, would be a difficult matter involving great cost. Not only will the market value of the naked land have greatly increased, but numerous and costly improvements will be encountered which will warrant heavy damages. In such a case it would be fair to say that, other things being equal, the old existing right of way is physically worth what a new one in the same vicinity would cost. In addition to this physical value, the existing right of way may possess strategical advantages and facilities for doing business which it would be impossible for the new one to acquire, and, if so, due consideration should be given to the value of these elements.

There are no present indications that either the National or the State Governments seriously contemplate the purchase of the railroads. Nevertheless, it is well to call early attention to the fact that an appraisal for some other purpose, as for regulating rates, cannot justly be used for determining values in expropriation of the properties.

Case 4.—Where the object of an appraisal is to determine the value of railroad property for the purpose of assessing ordinary taxes, the principles and practice appropriate will differ materially from those applying to the other cases considered. This is especially true with regard to right-of-way land. Unless otherwise provided by State statutes, railway land is subject to the same rate of taxation as other lands, and the amount of taxes assessed depends on the valuation placed on the land by the assessors. This assessed value of land may not be, and in fact usually is not, the same as the market value. The ratio between the two values, however, is presumed to be applied to all lands alike. In other words, the assessed value for taxation is rela-

Mr. Whinery. tive rather than actual. An appraisal of right-of-way land for taxation purposes, therefore, should be based on the assessed valuation of similar land adjoining it or in its vicinity. This does not mean, however, that it should be valued at the same unit price as such adjoining land, but rather that its actual value, when determined, should be multiplied by the ratio between the actual and assessed values which may be found to prevail in the locality. In determining value for taxation, the Courts have generally made it plain that neither the use made of, nor the amount of benefit or profit derived from, the land may be considered.

The question to be decided is, therefore: What is the value, other things being equal, of right-of-way land as compared with that of other land in its vicinity?

In seeking a general answer to this question, it may simplify the discussion to use for illustration a hypothetical case which is fairly typical of a majority of right-of-way transactions.

A owns a farm of 160 acres, the fair and reasonable market value of which, as a whole, and of similar land in the vicinity, is adjudged to be $50 per acre. For simplicity, it will be assumed that it is taxed on this full value. Through this farm a new railroad must secure a right of way, 100 ft. wide, requiring, say, 6 acres. The conditions are such that the three elements, fair market value, permanent damages, and temporary damages, are involved. It will be assumed that the parties cannot agree on the amount of compensation to be paid by the railroad, and that the right of way is condemned by a commission of disinterested, competent, and fair-minded men, who exercise their best judgment, after informing themselves of all the facts. They find and report that the market value of the land is $60 per acre, that the permanent damage is $600, and that the temporary damage is $140, making in all, $1 100. The question at once arises, why do they estimate the value of the 6 acres taken, at a higher price per acre than the admitted fair price for the whole farm; and is that action justified? It may be replied, that though it may be true that the severed land is intrinsically no more valuable than that which remains, common business customs sanction the higher valuation. The general analogy to wholesale and retail transactions may be instanced; also the familiar fact that when a tract of land is purchased *en bloc* and divided into smaller tracts or lots, these latter command a higher unit price than was paid for the whole tract. Again, fair market price is said to be that price established when both seller and buyer are equally free and disposed to deal. Now, if for any reason, B wanted to buy a selected part of A's farm, which is intrinsically worth no more than any other part of the farm, and is located so that its severance would not damage the remainder, it

is natural and reasonable that A should ask, and B should be willing to pay, a higher unit price than A would ask for the farm as a whole. It is equally reasonable that the land severed for the right of way should command a higher price than the farm as a whole. What that higher price should be is a matter of judgment, and it must be assumed that the commission exercised its best judgment in the matter. It must be assumed that its award for permanent and temporary damages is also fair and equitable. Mr. Whinery.

The transaction being closed in accordance with the award, the question in due time will arise, how shall the properties be assessed for taxation? Here, the State becomes an interested party, and her rights must be taken into account. The permanent damage of $600 was awarded on the ground that the remainder of A's farm is permanently injured and, therefore, that its value is decreased by that sum. When the tax assessor appears, A may reasonably claim that that sum shall be deducted from what his farm would otherwise be assessed for. The assessor accedes to what seems a just demand, and appraises the remaining 154 acres at $46.10 per acre, and proceeds to appraise the railroad right of way. Here some perplexing questions arise. He may readily decide that the property should be appraised on the value fixed by the Commission, but he discovers that even when this is done, the aggregate assessment on the whole of the property will fall short of the amount the undivided property has been previously appraised at by $540.60. In other words, that on such an appraisal, the State will lose the taxes on that sum. This would obviously be unjust to the State. Further study shows him that in order that the State shall receive the same amount of taxes as before, the permanent damages deducted from A's appraisal must be practically all added to what would otherwise be the appraised value of the right of way. In other words, permanent damages must be considered as accruing to the benefit and value of the severed land, in addition to what would otherwise be its fair market value. He, therefore, lists the right of way at $\$360 + \$600 = \$960$, or at the rate of $160 per acre, and, under these appraisals, the State will receive substantially the same amount of taxes as heretofore. The value per acre thus ascertained is 3½ times that of other land in the vicinity.

The ordinary tax assessor may not enter into such nice reasoning or computation, or reach a like result, but he might well do so, and the soundness of the argument, from the State's point of view, must be conceded.

The conditions described relate to a time closely following the acquirement of the right of way. The question arises whether the conditions then found continue into the future, say, 20 years thereafter. The market value of surrounding land may have increased or decreased

Mr. Whinery. in the meantime, and the naked value of the right-of-way land may have increased or decreased accordingly. The award for permanent damages, however, does not change with time. The injuries to the remaining land, from their very nature, must be regarded as permanent and continuous, and their value must still inhere in the right-of-way land. It is, therefore, still a factor to be reckoned with in appraising the property for taxation purposes.

Coming now to the application of these general principles, it would appear that a proper appraisal of right-of-way land for taxation purposes should be based on at least three elements of value:

First. The fair market value of similar land in the immediate vicinity (excluding, however, adjoining land permanently damaged);

Second. A reasonable percentage to be added for increased value due to selection and severance;

Third. The amount of the permanent damages caused by the taking of the right of way.

If in any given case the records of the original transaction were available and the compensation paid were properly itemized, it would not be difficult to arrive at a proper valuation; but, in practice, especially in the case of the older railroads, these data are hardly ever available, and the appraiser must exercise his best judgment, particularly as to the fair amount of the permanent damages.

In fact, it is found in practice that it is hardly practicable or even possible to consider each individual tract of a right of way thus in detail, and that it is necessary and desirable to formulate some general rule to be applied to the determination of the value of right-of-way land, either as a whole or to certain classes or local sections. This is the more permissible because the right-of-way land of any railroad is likely to be assessed as a whole, and a correctly framed scale of values is likely to give fair average results.

The simplest and, perhaps, on the whole, the best procedure is to assume that the value of the right-of-way land bears some fixed relation to the market value of other lands in its vicinity, and to apply some fixed multiplier of that market value to the right of way. Multipliers varying from one to three have been used in different appraisals, where the purpose of the appraisal has not been clearly defined.

The author states that it is a well-known fact that land for right of way usually costs from 2 to 2½ times as much as the market value of surrounding land. From the writer's experience (not, however, very recent), in well-developed farming country, he would say that these figures are very conservative, and that factors of from 2½ to 3½ would be more nearly correct; perhaps, 2½ would be a low average figure.

It would not be fair, however, to use this factor of cost as a multiplier for determining values for taxation, for it includes the elements of temporary damages and incidental expenses which, obviously, should be excluded from an appraisal for taxation. If we assume that these amount to one-fifth of the total cost, the proper multiplier would be 2, and we would have the general rule that for taxation purposes, right-of-way land should be appraised at double the value of other land in its vicinity. Mr. Whinery.

In the writer's opinion, it will seldom be found that a proper multiplier, determined in accordance with the principles here outlined, will fall below that figure.

It may be, and generally is, claimed by railroad men that the prices thus commonly exacted and paid for right-of-way land are excessive, and that such differences in value are factitious. The fact, however, that they have prevailed for half a century and over the whole country, whether the right of way has been secured by private purchase or by condemnation, would seem to indicate that the general ratio has a substantial foundation in fact.

The author refers to the fact that in the recent re-valuation of the railroads of New Jersey, where the purpose was avowedly to establish a basis for taxation, right-of-way land was appraised by the expert of the State Board of Appraisers at the same unit value as adjoining lands. The writer cannot but believe that if this appraisal shall be finally adopted as the basis for taxing that part of the railroad property, the State will fail to receive the amount of taxes to which it is justly entitled. The land (first-class) was appraised at nearly $47 000 000, but this embraced land for terminals, etc., the separate value of which is not given. Assuming that two-thirds of the whole was properly classifiable as right of way, which should rightly have been appraised at double the value of adjoining land, the State would lose, annually, taxes justly due it on somewhat more than $30 000 000 worth of property.

It is not asserted, of course, that the principles herein advocated will be applicable to every case for which an appraisal is called. Even in the absence of definite instructions calling for a different treatment, a great variety of conditions and circumstances may develop, which may require modified action in individual cases or classes of cases.

The writer's object has been to outline the general principles which, in his opinion, should underlie and control appraisals of this kind of railroad property.

F. Lavis, M. Am. Soc. C. E.—Mr. Wilgus is to be congratulated on the very clear and concise presentation he has made of the basic principles governing the valuation of railroads. He has covered the ground so thoroughly as to leave little opportunity for discussion, and, although the speaker can do little but concur with him, it is, perhaps, not inap- Mr. Lavis.

Mr. Lavis. propriate, in view of the present-day interest in this subject, to express this, and emphasize, if possible, some of the more important points that are made.

In a discussion of the paper* on this subject by Henry Earle Riggs, M. Am. Soc. C. E., the speaker pointed out some reasons why valuations of the railroads might not be an unmixed evil, as seemed to be generally assumed at that time, the conclusion of that discussion being as follows:

"First, that valuations properly made may be the means whereby confidence may be restored, not only in the mind of the general public, but in that of the investor; but, in order to obtain this result, the railroads should urge, with all the power they possess, the necessity of having such valuations made by a body of men, some of whom, at least, should be engineers, big enough to entitle their opinions to the respect of both sides, and thoroughly qualified by training and experience for the work.

"Second, that, as far as possible, regulation should be general or national, so as to avoid the complication of dividing all roads at the State lines, and of having different regulations in different States.

"Third, that there need not necessarily be any relation between rate regulation and rate-making. Rate regulation can well be confined to rates in the aggregate, rate-making applies to the adjustment of individual rates, and must necessarily be the work of men well versed in all the varied elements which control it and the particular conditions affecting the business of each particular road."

The paper by Mr. Riggs was an able discussion of methods of obtaining the cost of reproduction, but the author refused to recognize that the consideration of the so-called "intangible values" had any place in a physical valuation, and he did not consider that the purpose for which an appraisal was to be made should have any influence in determining the value of the property.

It is the discussion of these particular points by Mr. Wilgus which the speaker believes should be emphasized. He points out distinctly that the reason for making the valuation, or the purpose for which it is to be used, has an important bearing on the method of making it, and also states the principles which should guide an experienced man in making a reasonable estimate of at least some of the so-called "intangible values," or perhaps it would be better to say that he has outlined so completely the really tangible values as to have eliminated all or nearly all which can be called intangible, which are included in the unbreakable circle of argument in which it is claimed that the rates are based on values and the values on the rates.

It is shown in the first place how the appraisal of the individual items composing a railroad, without relation to their value as correlated parts of a whole, may be justified for taxation purposes, but is

* *Transactions*, Am. Soc. C. E., Vol. LXXII, p. 174.

not a proper method for determining the value of the property as a living entity, that the "original cost to date" method is untenable on account of the almost universal lack of records of any value and for other reasons, and the conclusion is that the "Cost of Reproduction New" is the only method whereby an appraisal can be made which will be fair and just to both railroads and public, and will give a fair value to the property as a whole and as a railroad, if it be properly made. Mr. Lavis.

Leaving aside the question of taxation, which is really a local issue, the valuation of the railroads is now to be made by the Interstate Commerce Commission principally in order to determine whether the capitalization is fair, whether the rates now being earned give a fair return on that capitalization, or as information on which it may base its judgment in regard to new capital requirements. To one with experience in other countries, where the regulation of the railroads is most jealously guarded by the Government and where it does not act either as a serious deterrent to development or serious inconvenience, this does not appear altogether undesirable or unreasonable, but, whatever one may think about this, it is begging the question to say that no valuation will give adequate values for these purposes. What we have to do is to admit that valuations are to be made practically and solely on this account, and determine how they may be made properly.

The application of any valuation of a railroad property to the adjustment of rates is, of course, complicated, and it can easily be imagined that, on first consideration by any one at all familiar with the intricacies of rate-making, the difficulties appear insurmountable. Suppose fair valuations are arrived at; suppose a fair return on this value is fixed, and the aggregate of the rates raised or lowered by a certain percentage to give this assumed fair return; how, it is asked, are the differences in management and the thousand and one other inherent differences in physical characteristics and conditions to be overcome? There would be no competent answer to this were each railroad to be taken as a unit or an attempt made to regulate individual rates, but, inasmuch as it would be difficult to change a rate on, say, the Pennsylvania between New York and Chicago without making a similar change on the Baltimore and Ohio, Erie, New York Central, etc., it seems impossible to use such valuations as may be arrived at for any other purpose than the regulation of the rates as a whole over a distinct section. That such a method of rate regulation is a practical one has already been recognized by the Committee of Presidents of the Eastern Railroads. For some time that Committee has endeavored to obtain permission to raise certain individual rates which were admittedly too low, but the opposition from the shippers has prevented favorable action by the Interstate Commerce Commission.

Mr. Lavis. The Committee, therefore, has now decided to ask for a blanket increase of a certain percentage on all rates throughout the Eastern territory, as there seems to be far less objection to the rates, *per se*, than to any change in the relation of certain individual rates to certain others, and this is quite in line with the speaker's conclusion in his discussion of Mr. Riggs' paper.

The trend of practical endeavor, therefore, as well as a common-sense view, seems to lead to the conclusion that the only adjustment of rates can be a blanket one, covering a large section of the country where prevailing conditions are generally similar, and to the speaker this seems to put the question of valuation on a basis where many of the objections, which may be and are quite properly raised, against valuation of separate roads or parts of them, can be overcome.

Most of the arguments against any theory of basing rates on valuation are founded on the inherent differences in physical characteristics, methods of management, local conditions, etc. In an address delivered before the Southern Commercial Congress, in April, 1911, by Charles Hansel, M. Am. Soc. C. E., it was shown that a higher or lower rate of gradient on two or more competing lines might materially affect their value. He assumed three lines, each 100 miles in length, the first with 0.3% grades, the second with 1.0% grades, and the third with 1.136% grades, and showed that for a tonnage of 10 000 per annum the capitalized value of the additional cost of hauling the tonnage on the two latter might amount to some eight or ten millions of dollars.

Of course, the assumption of two roads between the same termini with essentially different physical characteristics is the *reductio ad absurdum* argument. As a matter of fact, when there are two or more roads between the same termini, or which reach the same points, the rate between these points for the same class of commodity is the same, no matter what the operating conditions of the properties are. If the valuation of the property is for the purpose of purchase or sale, the operating value, as affected by the physical conditions or physical characteristics, should be considered, but, if the valuation is used as a basis for fixing rates between competitive points, it cannot be.

Such a case as that cited above is, from a practical standpoint, purely theoretical, and it may be admitted at once that, if there were any two such roads, no valuation would be a fair basis for fixing the rates on them. If the rates were fair for one, they would be likely to be unfair for the other; looking at the matter broadly, however, there can be no more reason in the valuations to be made by the Interstate Commerce Commission for comparing physical conditions or physical characteristics of competing lines than there is now. No two lines could be more dissimilar than the Pennsylvania and the New York Central between New York and Chicago, and yet the rates are

the same. If the Erie Railroad spends a large sum of money and makes improvements which will reduce its ruling grade to, say, 0.3%, it can hardly be expected that on that account it will be compelled to adopt a lower rate than it charged before, because it can operate more cheaply, or charge a higher one because it has spent a lot of money. Mr Lavis.

There is, perhaps, a certain class of individual rates between local points which are, and probably will continue to be, subject to investigation by the Interstate Commerce Commission or the State Boards. The regulation of these rates, if necessary, must inevitably be based very largely on the cost of service, and, as a basis for determining this, or at least as a starting point, there would seem to be nothing better than an adequate appreciation of the value of the property involved. It seems improbable though that there could ever be considered even, the proposition to fix rates separately on, for example, the Pennsylvania, the Baltimore and Ohio, the Erie, and the New York Central on the basis of the valuation of the individual properties, or even a combination of the values of the physical properties with the capitalization and earnings of each individual property; but that need not prevent the use of a fair valuation taken together with an appreciation of the cost of operation, as a basis for a general advance of rates which might be shown to be necessary in order to provide a fair return to the stockholders and an inducement for the provision of necessary new capital.

It seems to the speaker to be entirely outside the realms of practical discussion to consider for a moment the actual costs of any of the parts which go to make up the railroad as a whole, except as such costs might be a sidelight on their value to-day, or we would never get anywhere. Take, for instance, right of way: some of it may have been given free; it may have been paid for at ten times its value; it may have been obtained by right of eminent domain and the legal expenses charged to something else. Rails were bought at $20 or $40 a ton which would now cost $30. A tunnel was built at a cost to the railroad by which the contractor lost money; another at a cost which allowed a good profit. The whole road may have been bought at a foreclosure sale and so on, almost without end.

The speaker was asked some little time ago to prepare a basis for the determination of unit prices to be used in connection with the valuation of a certain railroad. In looking up actual costs of rock excavation to this road, many contracts were examined dating from 1880 to the present time, the prices ranged from 65 cents to $2.50 per cu. yd., and all within a comparatively narrow range of territory. This, of course, is nothing new, but surely no one with any experience could expect to base the value of the rock excavation on, say, the

Mr. Lavis. Erie Railroad as it exists to-day, on such original costs of parts of it as might be found by an examination of the records. There are altogether too many complications to make it possible to consider original costs, except such as those in which all the governing factors are known which may be used as a guide in determining present-day values. A rock cut may have been taken out originally at $1 per cu. yd., and a slice taken off the side for another track might easily have cost $2, or even under certain conditions less than it did in the first place. It seems to the speaker that, looking at the matter from a practical standpoint, these and innumerable other complications of a similar nature cannot be considered now. We can only consider what it would cost to take that cut out if we had to do it to-day and get it in the shape it now is, and that is quite within the range of the ability of practical men. Really, the cost of reproduction new is the only logical, practical way that will give results which, at least, will be as fair to one road as to another, and as fair to the public as to the railroads.

In many countries where the Government has retained full control over transportation enterprises (and, after all, if at all fairly exercised, this is far better than either unbridled private enterprise or Government ownership), the amount of the capitalization which will be recognized by the Government is definitely fixed. The first cost is determined and approved during and on the completion of the construction, after a satisfactory investigation of the books, and additions made yearly to cover the additional capital expenditures. In the United States, for many good and sufficient reasons, and others equally bad and insufficient, we have let the railroads alone, and now the Government is trying to regain the control it should never have relinquished. As long as this control is fairly exercised, we shall be all right. To exercise it fairly, those charged with it must have knowledge, and one of the things they should know is the value of the property they are controlling.

This value can be obtained fairly, but, it seems to the speaker, only by putting everything on a common basis. There can be no fooling with such questions as "right of way has no value because it has been given to the railroad," or that it "has not increased in value," or that "if we wanted to reproduce it to-day we would not pay a farmer three or four times the acreage value if we cut through between his homestead and the rest of his land." Such speculations as these open up vast vistas of discussion to which there is no end. The "Cost of Reproduction New" is entirely practical and one well within the range of the understanding of any fairly intelligent person. To obtain it fairly needs practical experience, training, and a knowledge of railroad conditions, and Mr. Wilgus has done a service in calling atten-

tion to some of the matters which, if the work is to be done properly, must receive most careful consideration from those who he truly says are "burdened with a Herculean task" in undertaking to value all the railroads of the country. Mr. Lavis.

The necessity for the employment of competent men is pointed out, and this fact should be emphasized, for though it may be generally admitted that a certain number of competent engineers are required, it is not always conceded that railroad as well as engineering experience is required in many of the comparatively minor, or at least intermediate, positions.

Even the first step, the compilation of an accurate inventory of the property of a railroad, must be taken by men in the field who have become capable by long association with railroads in the making and in their subsequent maintenance. Take, for instance, the one item of the earthwork on a railroad, the questions of settlement of embankments built across marshes, the settlement of the embankments themselves, the estimation of slides, the classification of the material, haul, the general seasoning of the whole roadbed, etc., cannot be properly answered or values estimated by any but men of experience who can and do judge the conditions on the ground. The task of making an inventory and fixing prices of the measurable items, although one of great importance, is well within the range of an organization which can be developed from the large number of competent engineers available who have had fairly long and wide experience in railroad construction.

The really important matters pointed out by Mr. Wilgus, however, are the estimation of the value of the two stages of the development of a railroad preceding and succeeding the actual construction period, and the speaker believes, with him, that an equitable valuation of the costs to a railroad during these two periods is not an impossible or impractical task, and, if fairly made by men of widest experience in railroad affairs—not merely engineers with only construction experience—will largely cover the so-called "intangible values."

Until very recently the speaker thought that the position taken by Mr. Wilgus, and as expounded in this paper, was so obvious that there could be little chance for argument, but there still appears to be a large number of otherwise intelligent people who continue to think that the valuation of railroads is necessarily different from the valuation of any other business property, in other words, that the valuations to be made are to be simply an inventory of ties, rails, locomotives, etc., with a price for each, and that the "good will," etc., is to be ignored. We have, perhaps, rather ignored the discussion of the "intangible values," because we have not been able to see quite clearly how we were going to estimate their value, but that may be due to the same state of mind we are often in, when approaching any

Mr. Lavis. problem of importance which may come up. We may have a bridge, or tunnel, or anything else, to design and construct. When we start we may not know exactly how it is going to turn out, even though we know we can do it; we know there are difficulties; we know that the first tentative designs will be all changed; but we also know that if we keep at it long enough and with a sufficient degree of intelligence, backed by experience, we shall work it out. It seems to the speaker to be the same way about valuation. Proper consideration will show that many of the so-called intangible values have considerable substance, and a fair determination of their worth can be arrived at by a proper process of intelligent application. Mr. Wilgus has drawn a broad outline of the matters to be considered; it is for those who have the work to do to fill in the details.

There might be endless discussion, of course, in regard to what these values should be, but it looks as if we had come to the point where some one will have to decide. It is not a question of absolute right, but of coming to a decision which will be as fair as possible to all concerned. There is nothing impractical in this, the absolute right of the majority of disputes is seldom reached, most decisions are compromises or, at least, the best judgment of some man or body of men, and it is usually only necessary that we be assured of the competence and impartiality of the tribunal to permit us to acquiesce in the decision. It is necessary, however, that we be assured of the competence as well as the impartiality, and that all pertinent matters will receive due consideration. The necessity of this latter should perhaps be emphasized most particularly in connection with the estimation of the costs or value of those items which exist but are not easily or physically measurable.

Mr. Churchill's remarks seem to convey the inference that he prefers the method of "original costs", and that he believes this method to be practical.

As the writer understands the situation, the ruling of the Courts and of the Act creating the Interstate Commerce Commission makes it necessary, or at least desirable, that original costs shall be shown wherever possible, but only as a guide to the value of the estimate showing the "present fair value."

The *Railway Age Gazette** seems to express the prevailing opinion in regard to the present fair value quite clearly, as follows:

"When property is taken under the power of eminent domain, the value on which the compensation paid for it must ordinarily be based is its value at the time it is taken. The amount which it has cost its owner may be considered in the endeavor to ascertain its present value; but it is the payment of its present value, and not of what it has cost its possessor, which constitutes just compensation. On the

* September 12th, 1913.

same principle the valuation of a public utility to establish a basis for the regulation of its rates must, it would seem, be based on the present value of its property. That this is the correct legal view certainly seems to be a just inference from language repeatedly used by the federal courts." Mr. Lavis.

If the original contracts, agreements, or book costs, can be found, showing exactly the cost to a railroad of a certain part of its property, it is, of course, very good evidence tending to prove the value. The difficulty of applying these values, however, and one which it hardly seems necessary to point out, is in identifying the structures covered by the original costs with those existing to-day. Is there a single cutting or embankment on any railroad anywhere in the same condition it was 5 years ago? to say nothing of those on which the original work was done 75 years ago. (There were nearly 7 000 miles of railroad in operation in 1850, mostly in what is now official classification territory.) Even if we had exact records of the original cost of each cut and fill and of all the work done on it since, which should properly be charged to capital account, would that give a "fair value" for the property in use at the present time, and on which the regulation of the rates and of the amount of new capital requirements are to be based?

The fact of which we, as engineers, are all very proud, and which is undoubtedly true, as Mr. Churchill says, that most, if not all, contracts for railroad construction are honestly and fairly made and executed, does not seem to the writer to be any necessary criterion that they represent a fair value of the property in use to-day.

There is also another objection to their use, that, from the standpoint of the public, which rightly or wrongly looks on the railroad as an opponent, these contracts will be looked on as *ex-parte* evidence. As evidence tending to prove the correctness of the inventory, for showing exact quantities, classification, character of materials, etc., every jot of evidence shown by the old contracts and plans should be sifted out and used for what it is worth, and this is one of the smaller tasks in making a correct inventory, which, in itself, might be called stupendous, except that we have to be somewhat chary of such adjectives nowadays when nothing seems too large to be undertaken.

It is entirely feasible and a matter of common practice to base a fair present-day value on the consensus of opinion of competent men engaged in practical work of the nature under consideration, and whose experience entitles their opinion to weight. Any other value, say that of 5 years ago, or 10 year hence, or even the actual price paid, is open to controversy as not being fair. If the value of 5 years ago is taken, why not take it for 10, 20, or 50 years ago? If a railroad is to be criticized, as it may be, for awarding contracts for

Mr. Lavis. supplies at exorbitant prices to friends of officials, even if its construction contracts are fair and just—and who shall say they always are—why is it not also entitled to credit when, for any reason, it gets supplies or construction done for less than the present-day market value, as it sometimes does? All these matters, however, invite controversy, but a fair valuation, made by competent men, based on the present "cost of reproduction new" is practical, can be defended, and, if properly made, will be accepted. It seems to the writer doubtful whether any other value can or will be.

The point brought out by Mr. Churchill, that the records of all variations shall be kept in the forms of accounts prepared by the Interstate Commerce Commission, would seem almost to bar the use of original records, except for their worth as evidence tending to show the present fair value.

Mr. Crehore. WILLIAM W. CREHORE, M. AM. SOC. C. E.—This admirable paper shows the author to be thoroughly familiar with his subject, which he treats in a comprehensive and exhaustive manner not to be expected from any other than a railroad official of wide experience. On some of the special points, however, which are matters of opinion only, a layman may be permitted, perhaps, to differ from the author's conclusions without exposing himself to the charge of presumptuousness. On this basis, the speaker wishes to take one exception to the opinions advanced in the paper.

In enunciating the basic principles of procedure and the several ways of determining the physical value, Mr. Wilgus refers to the method known as "Cost of Reproduction, Less Depreciation," and states that, for rate-making purposes, it seems to him that the physical depreciation should not be deducted from the cost of reproduction new. His reasons for this are "that all expenditures for renewals and repairs should be charged to working expenses, and not to capital," and that "normal depreciation is not to be treated as a wastage of capital, but as an element in the cost of operation that is covered by the rate." He then goes on to state that the law requiring "that valuations shall be revised from time to time as improvements and other changes are made, in effect prohibits the deduction of depreciation, as otherwise the constant addition of amounts expended in the replacement or renewal of items that had been included in the valuation at their depreciated price, would be a violation of the rule of the Interstate Commerce Commission that operating expenses should not be charged to capital."

The fact should not be lost sight of that betterments and improvements, when paid for out of income, are just as much property as if paid for out of capital, and, as assets of the company, they should be included in the inventories made from time to time. It is the evident

intention of the Interstate Commerce Commission to draw a definite and distinct line between funds used for extension and enhancement of railroad property, and those used for the prevention of undue depreciation of existing property; in other words the distinction is between repairs and renewals necessary to maintain the original investment at its full efficiency, on the one hand, and such betterments and improvements, on the other hand, as constitute permanent additions to the original investment. In order to protect the stockholder, the property paid for by his original investment should be kept up by repairs and renewals as nearly as practicable to 100% efficiency, or a fund should be established to reimburse him for the difference. Mr. Crehore.

It is customary to look at depreciation as a stockholder's liability, but, in truth, it is his liability only because he has received in dividends at some previous period the money which should have been expended to keep the property up to 100% efficiency, or which should have been put into a fund to be used for that purpose. It is unquestionably the moral duty of the management to keep the company's property up to its full efficiency, or to establish out of the income an equivalent reserve fund. When this is done, there can be no liability for depreciation on the part of the stockholder. Whenever this money is paid to him as dividends, however, instead of being put into the property, he is then actually receiving back part of his original investment, on the instalment plan, as it were. If, then, the stockholder has received this part of his investment back, it certainly remains no longer among the assets of the corporation; hence, to obtain a proper value of the assets, for rate-making purposes, or for any other purpose, the amount of this depreciation should be deducted. The opponents of this view certainly will not contend that rates should be made proportionate to assets which do not exist in the corporation.

The author's view that depreciation should not be deducted is based on the stockholder's liability to be called on at some future time for fresh capital to put the property back to 100% efficiency. Until that time comes, however, and the stockholder does thus put his money back into the property, is there any reason why the rates should be large enough to pay him dividends on that portion of his investment which he withdrew from the corporation, as well as on that which he still has in it? Or if, as is usually done, the property is put back to full efficiency by the use of future income (that is, through an issue of bonds), is there any good reason why the stockholder should be the sole beneficiary from that operation which has cost him nothing? Does it, in the first place, seem just to make the public pay rates high enough to cover dividends on the depreciation of the property, when the equivalent of that depreciation has already been paid back to the stockholder? In the second place, is it just and right that the rates should be high enough to cover dividends on the original value of the property in-

Mr. Crehore. cluding depreciation, and, at the same time, high enough to retire an issue of bonds necessitated only because of the withdrawal of the deprecation reserve fund by the stockholders?

To make the rates high enough to cover future betterments and improvements and to lay the money aside for this purpose is one thing; but to make such rates and then devote the money thus raised to dividends based on the original value of depreciated property cannot be justified. The stockholders should not expect to "have their cake and eat it too." To argue that this is customary does not justify it as good practice, nor does it appeal to the fair-minded gentlemen composing the Interstate Commerce Commission as being either good theory or good practice. Any corporation which is handled so as to allow its property to depreciate without providing a fund out of the income as the equivalent of this depreciation, cannot claim that the full investment of the stockholders is represented in the assets of the corporation, and, therefore, cannot expect to be allowed a rate based on fictitious property just because it has been capitalized.

The market value of any property other than a public utility, that is, any property unregulated by law, is a direct function of its income, fluctuating with the income. This market value apparently is unrelated either to the intrinsic value of the company's assets or to the amount of capital invested. Investors look only at the rate of income and the safety of the investment. If, for instance, the stock of a reliable concern pays 40%, this stock cannot be bought at par; but the market price will be well up to a point where dividends on it will be normal.

Now the difference between this market value of the "going" concern and the actual intrinsic value of its real assets is ascribed to the "good-will" of the business, or the "franchise" value, as it may be called in the case of a public utility, meaning thereby the value of its intangible assets. If the business is highly prosperous, the good-will or franchise value is correspondingly great. The actual intrinsic value of a going concern's real assets does not change merely because of the advent of prosperity or the reverse, but the good-will or franchise value does vary for this cause. With some very highly developed monopolies, the good-will value of the business is the largest asset, the intrinsic value of its property being merely incidental.

This being so, it is evident that the problem before the Interstate Commerce Commission, in regard to railroads, is to reverse the natural operation of an unrestricted monopoly. Instead of "charging all the traffic will bear" and determining the good-will value of the business by the amount of income, as is common with a private corporation, the Commission's problem is to ascertain the value of the assets (intangible as well as tangible), and then to make the income conform with it by virtue of the rate-making power. This difference be-

tween a public utility and a private corporation seems generally to be unrecognized. In the working out of this problem there is very little to be learned from the example of private monopolies, excepting as they may be said to teach "how not to do it". In the Commission's problem it is necessary to prevent all exaggeration in respect to the good-will or franchise value in determining the value of a railroad's assets. Mr. Crehore.

A railroad is a monopoly created by the law-making power primarily for public uses. A private corporation, on the other hand, is created primarily to make money for its stockholders. A railroad's charter is granted by a special agreement with the Legislature, and gives it an exclusive monopoly in its own territory, except at and near the terminals. Such a monopoly must of necessity be regulated by some common authority, in order that the communities through which it operates shall not be discriminated against in comparison with those similarly situated on other railroads, and for the further reason that the railroads are practically indispensable to all business interests. Each year sees the business of the country more and more dependent on the railroads for the interchange of commodities.

For these reasons, also, it is necessary that the public authority in control of the railroads should endeavor to have the rates fixed as low as is consistent with the value of the capitalist's investment. This investment, however, certainly does not comprise betterments and improvements which have been paid for exclusively out of rates (which, for this reason, are excessive rates) charged to the public. In this respect a railroad's opportunities to make money for its stockholders are far greater than those of a private corporation competing for a livelihood; and railroad investors have so long been accustomed to the advantage they possess for making the public pay for anything they want, that it will not be an easy matter to attract them when these opportunities are removed, although the return on their actual investment should still remain as good as, or better than, that of corporations in private business.

Neglect to provide depreciation funds is in the same category, both financially and economically, with the omission to establish sinking funds for outstanding bond issues. Both practices have brought about an enormous inflation of values by the introduction of fictitious capitalization. Bonds have been left outstanding long after the property or equipment purchased with their proceeds has become useless; or, if refunded, the effect is the same, because stockholders claim their share of the earnings beyond the lifetime of the property to produce which their proceeds were applied. Whenever an issue of bonds is refunded, which ought to have been paid off by a provision out of the earnings, its claim is added to that of the new bond issue for a

Mr. Crebore. share of the future earnings. Such bonds as are not co-terminous with the life of the property originally purchased with their proceeds, serve to increase the burden of inflation, because the security that was once behind them is abandoned, useless, or obsolēte. To provide income for bonds like these is to carry a fictitious investment on the books, and with every refunding of debts that ought to be retired, the load of over-capitalization receives a new increment.

It has come to be the popular conception that to capitalize anything is to provide an income for it. But capital is wealth; therefore, when an income is provided for something which does not exist, there results a form of capitalization which adds no wealth to the property at all, but is fictitious capitalization or over-capitalization. It provides an income for fictitious investment. Property which has become obsolete or superseded by other property ceases to have any earning power, and is no longer entitled to any income. Hence the bonds, from the proceeds of which it was originally purchased, must be retired by the earnings of the period covered by the life of the property in order to prevent over-capitalization or inflation.

An exact compliance with this theory is, of course, not possible in practice. With the railroads of the United States, progress and development have caused such unforeseen changes in recent years that it has not always been possible to arrange bond issues which should terminate with the life of the property represented by them; but there could have been, and should now be, made a more vigorous effort to retire such issues as have outlived their usefulness, by payments out of the earnings rather than by refunding, and it must not be expected that the public will permit rates to be increased in order to enable the railroads to make a readjustment which has been necessitated by excessive rewards to stockholders. The stockholders have "eaten their cake" and that of the bondholders too, and their efforts to get the public to feed the bondholders no longer deceive the majority of those interested.

The great incentive behind this movement for the valuation of existing railroad property evidently lies in a desire to have more complete and definite knowledge as to the size of this load of over-capitalization carried by the railroads. The extent to which progress and development have contributed item after item to the load of over-capitalization in recent years is not realized by many; and the inflation itself is totally denied by others. Naturally, there will be some among the latter who will be strongly impelled to complicate the valuation work, and to seek out every possible pretext for making the assets, both tangible and intangible, look as big as possible. It should not be inferred from this statement that Mr. Wilgus is credited with any but perfectly sincere and honorable motives in his elucidation of the subject.

Throughout the paper he has repeatedly stated that the method of obtaining the physical valuation should be chosen with reference to the purpose for which the valuation is made; that is, for purposes of rate-making he would recommend a method giving a different result from that obtained by the method he would recommend for the purpose of selling the property. Perhaps still another method might be recommended for purposes of taxation. Much has been said recently about the increasing burden of taxation on railroad properties, and there is no doubt a tendency on the part of local authorities all over the country to assess railroad property more nearly at its true value than has been customary in years gone by. Mr. Crehore.

Without in any way begging the question of physical valuation, the speaker takes the ground that the easiest and simplest way out of a complex and difficult situation, and one that would wipe out an immense amount of inflation, would be to order each railroad to put its own value on its property of all kinds, and to have it understood that the same value would be used in assessment for taxation as well as for acquisition of the property or for any other purpose. In other words, if there was any inclination to place a low valuation on the property for purposes of taxation, this would be counteracted by the knowledge that the Government would use that set valuation for rate-making purposes and for acquisition if desirable. With the aggregate of all these self-imposed railroad values thus put before it, the Interstate Commerce Commission could then determine fair and equitable rates based on these valuations. At least, if the rates thus determined were not fair and equitable, the railroad companies could not complain of the valuations on which they were based.

Our whole system of direct taxation is cumbersome, discriminatory, and unjust, putting a premium on shiftlessness. The man who keeps his property in good repair, his buildings and fences in order and well painted, is assessed far above his neighbor whose acreage is the same, but whose buildings and fences are dilapidated and broken down. If the estimate of each was accepted as the value of his own property, and if such valuation was registered in the public records to be used for all purposes, including taxation, the authorities would be relieved of a vast amount of burdensome detail, and if any injustice were done, the victim of it would have only himself to blame.

It is a poor rule that does not work both ways. What a boon such a system would be to the railroads for purposes of acquiring rights of way for extensions! Condemnation proceedings could be avoided, untold agents' commissions could be left out of consideration, and, best of all, an exact estimate of the cost of any proposed right of way could be obtained in advance merely by consulting the registered values of the property which it was desired to condemn. If the law

Mr. Crehore. authorized the condemnation, then the owner of the property would be obliged also by law to sell at his own registered figure. If property owners were permitted to change their valuations as often as once a year on a date fixed by law, and, when they failed to alter them, if the last previous valuation should be held to be valid until a new one was submitted on the regular date fixed for the purpose, speculation would be beneficially regulated rather than checked, and to the extent of the variation in taxation the State would share in the speculation, which is as it should be.

Under a general system of this kind applicable to all corporations and individuals alike, the unearned increment on unproductive but well-located property would be automatically and largely diminished. In any event, the full import of this feature would be shared by the State, and any tendency to exaggerate it would be checked by the proportionate rise in taxes. The author very justly complains of the excessive prices usually paid by railroad companies for property to be acquired for extensions and betterments; but, under the system just described, railroads would have to pay for such property no more than anybody else. Thus a prevalent cause of over-capitalizing railroad property would be removed, and not only would there result a relief in the financial burden, but a lower basis for rate-making purposes.

It is because of the very eminent fairness of this method of valuation that it is not likely to be popular. Property owners like to collect damages from some one when under compulsion to sell what is their own at a fair price for the public benefit. In fact, when a railroad is the purchaser, they too often look on the transaction as more beneficial to the railroad than to the public. At least they know that the railroad company is more likely to bid high for their property than any other individual purchaser, because land is capital, and the railroads are paying very high premiums for capital in any form. The intense sentimentality over property rights so prevalent in the United States would be sadly shattered if a man's rights to his property were reduced to just what he himself made them, and was able to pay for. As it is now, a man's property rights (within certain limits) are anything he chooses to think they are, and he does not have to sustain his exorbitant rating of them by one single item of expense beyond that of his neighbor who is similarly situated, but whose ideas are more moderate. Property owners in this country to-day are a highly privileged class, but are placed on a most unjust and discriminatory footing with respect to each other on account of the present system of direct taxation which is without uniformity, unsupported by reason, easily responsive to corrupt influences, and, most of all, is unstable or unreliable for revenue-producing purposes. The burden falls most heavily on those who refuse to take dishonest advantage of the system's weak points.

The important question in rate-making seems to be, not what is the intrinsic value of the property, but rather what is the capitalist's actual investment, and what portion of the earnings should be allowed to be capitalized and to become a basis for further dividends to be met out of the rates. It will be admitted that the rates must cover, in addition to all administrative and operating costs, (1) repairs and renewals necessary to keep the property up to its full efficiency, or the equivalent in the form of a fund for the protection of the stockholders, and (2) a reasonable return on the capital actually invested. To increase the rates beyond this in order to provide betterments and extensions is no different whatever from paying the stockholders larger dividends to enable them to reinvest immediately in the business, because, eventually, these betterments and extensions are capitalized and handed to the stockholders as a present. Of course, money for betterments and extension does come from previous dividends, either of these or of other stockholders, in this or in other business; but the question is, what dividend rate ought to be considered sufficient to enable the stockholders to reinvest the needful amount in betterments and extensions and have something left for themselves. With a private corporation the answer is, make as much money as you can; but with a public utility the object is to serve the public just as cheaply as possible, and, therefore, the problem begins with a determination of the minimum return which can be offered to attract capital. Mr. Crehore.

It has been said by railroad financiers testifying under oath that without the practice of capitalizing earnings and offering stock bonuses with bond issues, capital could not be attracted in sufficient quantities to take care of the necessary improvements in railroad operation. These statements are doubtless true, and indicate the extreme competition for capital at present prevailing in the United States. It would seem that capital ought to know its own interests well enough not to demand such large rewards that the business itself must eventually be throttled in order to satisfy its cupidity. This situation results from an interference with the natural law of supply and demand. As the wealth of the country gradually becomes concentrated in the hands of fewer individuals, the amount of capital outside of their control becomes less. All capital is wealth of some sort. As these people absorb an increasing proportion of the total wealth, they acquire control of a correspondingly increasing proportion of the total capital, and automatically with the growth of their monopoly the available sources of capital diminish. Under such competition for capital as results from this monopolistic control, it cannot be expected that railroad rates will be kept low if all the demands heretofore mentioned have to be supplied from the earnings.

The President of the Pennsylvania Railroad Company issued a statement on May 12th, 1913, in which he said:

Mr. Crehore.

"In England the policy of railroad companies has been to pay out currently to stockholders nearly all of the net earnings, and provide for all improvements out of the proceeds of sales of capital stock. If the investors in the stock and bonds of the Pennsylvania Railroad had supplied directly all the money which has been invested in the transportation property of this Company, and if they received the entire annual net earnings from the operations of such property, they would today be getting only 4.83 per cent. upon their actual cash outlay."

Two conclusions may be drawn from this statement: one is, that if capital can be obtained on such a basis in England, it can be so obtained in this country from England by removing from our properties that most objectionable feature, over-capitalization or inflation; the other is, that if the capital for the betterments above referred to did not come from the Pennsylvania Railroad stockholders it must necessarily have been collected out of the public, or (if through bond issues) is now being collected out of the public. In other words, the difference between our method of financing railroad extensions and England's method is, that over there the capitalist puts up all the capital and receives a fair return for it, and here the public puts up most of the capital and makes a present of it to the capitalist, not only getting nothing in return for it except the improved service, but also paying rates large enough to cover dividends on the gift as well as on the capitalist's actual investment. If prevailing methods are persisted in, the logic of the situation will force an answer to this question: in financing a railroad, if the rate-payers are to furnish the lion's share of the capital anyway, what is the use of having any stockholders at all? They are merely an incumbrance.

About such a state of affairs comment is superfluous; a complete change in the system is called for. The reform has been well inaugurated by the authoritative movement to obtain a careful and complete physical valuation of railroad properties, and this movement should have the earnest and candid support of all who are interested to see better times for the railroads as well as for the communities they serve. With the knowledge thus gained, the next step will be to eliminate the load of over-capitalization now carried and to begin retiring bond issues out of the earnings, instead of refunding them and allowing their share of the earnings to pass to the stockholders. The class which has so long been getting something for nothing must be taught by the removal of such opportunities to be satisfied with a fair return on its investment.

To correct a misunderstanding which seems to have arisen in regard to the speaker's proposed system of fixing property values for taxation and other purposes, it should be said that by this system there would be no prohibition against any individual placing his valuation figure as high as he pleased. It has been suggested in this discussion that

it would be a great injustice to a farmer to take a strip of his land for railroad purposes at the same rate of compensation as he would ask for the whole property. Of course it would. A strip dividing his property for any purpose, whether for a railroad or not, would damage what remained to him to a certain extent, but there would be nothing to prevent him from putting a valuation high enough to satisfy himself on that portion of his property through which it was at all likely that a railroad would pass, neither is there any reason why he should not place a higher value on some parts of his contiguous possessions than on others, and have it so registered. The only requirement imposed on the farmer by the system would be that he should pay taxes according to his own valuation. Mr. Crehore.

This would not be the hardship that some seem to think. There would be no general increase of taxes by an adoption of this method; the total amount collected for public uses will not vary because of a readjustment of values every year. The total amount of levy on a community remaining the same, the readjustment of values would mean merely a redistribution of the tax levy to correspond with the readjustment, which is as it should be. If a man thinks that his property is worth more than his neighbor's, he should be willing and ready to sustain his rating by paying proportionately greater taxes. The speaker cannot conceive anything unfair in such a method of taxation. The injustice to a community comes from announcing and maintaining values which are fictitious and misleading, or at variance with each other—low taxable values on the one hand and high selling values on the other. The merchant who asks one price from one customer and another price from another has a poor standing in any community. A sells property to B at a certain figure which both agree to keep secret. The newspapers, in the interests of speculators in the neighborhood, announce the sale at a figure very much higher than—perhaps twice as high as—the actual payment made by B, thereby misleading all property owners in the vicinity as to the real value of their own investments, and scaring off prospective purchasers or lessors who might have been attracted by a knowledge of the correct values prevailing in that community.

Discrimination in some form or other is at the bottom of all our industrial and financial troubles in these days. The injustice of our present system of taxation lies in recognizing one value for taxation purposes and a different value for purchases, and in discriminating between property holders who are similarly situated. Such a system promotes underhand work, and the tendency is to throw the burden of taxation on those who are not so well equipped as others to battle for their rights. If those who adhere in blind devotion to the present system would take into consideration the confusion it makes, the

Mr. Crehore. wrongs it perpetrates, the corruption it invites, and the false swearing it occasions, there would be a different feeling in regard to making a change.

As to what proportion of the betterments and extensions to railroad property should be provided from the proceeds of the sales of capital stock, and what part should be paid for out of the earnings—in other words, as to what extent surpluses should be capitalized—it should be understood that the speaker's whole contention applies to public service corporations regulated by Governmental authority, and not to Government-owned enterprises. Of course, where there are no stockholders, as in the latter case, it is proper that the rate-payers should furnish all the capital needed, as they are the sole beneficiaries of the increased earning capacity due to the betterments. The rate-payers, then, being the owners, whatever is done with the property redounds entirely to their injury or benefit as the case may be.

In the beginning it was assumed by the writer (and this assumption has been confirmed by the author) that the subject of the paper was based on the question: What is the proper way to ascertain the true physical value of railroad property; and only incidentally included the question: Shall this intrinsic value be used for the purpose of rate-making or not?

The writer's stand on the first of these questions was and is that a proper physical value of the assets can only be obtained by finding the cost to reproduce at prevailing prices and deducting a proper amount for depreciation, and that this resulting valuation should be used for all purposes where the correct physical valuation is called for. When, however, the correct physical valuation has been found, there still remains the question whether rates should be based on that or on something else. These appear to be two separate and distinct questions, although several of the parties to this discussion have treated them as if they were interdependent.

The utter hopelessness of getting a fair physical valuation by the Original Cost Method and the stupendous amount of work involved in getting it by the Cost to Reproduce less Depreciation Method was so impressive as to cause the writer to suggest the alternative of letting the railroads put their own valuation on property of all kinds. And yet—whereas an accurate value of the property could not possibly be ascertained by the Original Cost Method—there would be no difficulty in showing from the books just what money each investor had paid into the treasury; and, in the case of a public utility property, it is contended that this, taken together with a reasonable portion (not all) of the value of betterments and extensions, should be the basis of the investor's return paid to him out of the rates, the public being the beneficiary as to all the remainder.

Mr. Humphreys.

ALEXANDER C. HUMPHREYS, M. AM. SOC. C. E. (by letter).—The writer is in complete agreement with Mr. Wilgus' statement that the task of valuing the railroads of the United States is Herculean. He has seen nothing to lead him to think that our politicians have any adequate conception of the magnitude and the almost, if not quite, insurmountable obstacles in the way of a competent solution of all the questions involved.

There have been some expressions from the Commission charged with the chief responsibility, to indicate that even its members do not fully appreciate the grave responsibility which rests on them.

In addition to the inherent difficulties, one has to face what the writer believes is a too common fault in the United States to-day, fear —on the part of those directly interested—of criticism and denunciation from an uninformed and prejudiced public.

Already men have been appointed to positions of influence in connection with this work who have demonstrated that they are incompetent, and, what is worse, are willing and able to labor for the destruction of legitimate property rights.

This and much more that might be said indicates that we have not to-day in the United States a proper background for these appraisals. There is need of an effective scheme of public education, not by indirection, but frank, fearless, and in the open.

Our Courts, public officials, and professors and students of economics should be included in the classes of those to be educated. The conflicting and often faulty opinions delivered by our Commissions and our State and Federal Courts demonstrate that we of the laity must not submit too subserviently to the opinions and decisions which are quoted for our control. We may have to submit temporarily in cases at issue, but we should never surrender our beliefs where we know that we, as engineers, are more completely and accurately informed than the theorists who attempt to control us. We must patiently, persistently, courageously, and openly combat the theories which we believe to be founded in error or on an incomplete survey of all the questions involved.

In order to meet those who are thus engaged in controlling the situation, however, we must be more at one among ourselves. The fact is that on some of the questions at issue engineers are not in complete agreement.

Thus the Commissions and Courts are given the opportunity to choose between opinions at variance, and so are encouraged to pick and choose, item by item, until there is consolidated all possible features which are unfavorable to a fair solution of this valuation problem.

Another obstacle to a fair and consistent system of valuation is pointed out by Mr. Wilgus: the widely varying laws of the several

Mr. Humphreys.

States, not to speak of the widely varying interpretation of these, often ambiguous, laws.

Unquestionably, Mr. Wilgus is correct when he states that, as a general proposition, valuations cannot be determined accurately and fairly through reference to the records and books of account extending back through the years. It is not difficult to explain, to those qualified to understand, why this is the fact—but the fact has to be met, apart from the question of an adequate reason therefor.

Nothing could be further from the truth that, because a railroad or any property of magnitude can be inventoried, even if accurately and completely inventoried, the valuation can be determined by the inclusion of the items thus inventoried. Omissions and contingencies are not thus covered. Surely no engineer who has had any broad experience in construction could honestly so claim.

It is often the contingencies, lost to sight in the completed work, which add materially to the cost, and this outside of such overhead charges as preliminary or initiation expense, interest during construction, administrative expense, cost of procuring capital, etc., etc. For instance, if an appraisal should be made ten years from now of the New York Central Terminal, would an inventory of the existing structures disclose the legitimate and necessary cost of this great undertaking? This point is well developed in this paper.

One of the most difficult features involved in public service appraisals is that of depreciation. This subject is misunderstood by many who claim the right to speak authoritatively thereon.

If the accounts are accurately kept, so that proper discrimination is maintained between charges to construction and to maintenance, no deduction should be made for depreciation from cost to reproduce new.

Troubles in this matter have, no doubt, in part been occasioned by the more conservative practice of late in keeping accounts so as to spread the cost of final renewals ("depreciation") more uniformly over the period benefited. This leads those on the outside—and sometimes those on the inside—to think that we should deduct the assumed or estimated accrued depreciation from cost of plant. A depreciation reserve is required only to point out to us year by year that there may be certain charges against income not shown by the current expenditures and so warning us not to over-estimate our profits; but, if final renewals have not been cared for completely in the current expenditures, then there is the liability therefor, resting against the proprietors, which must be met when parts of the plant come to be renewed. All repairs and all renewals, whether current or deferred, are chargeable against income, and so must be met by the rates. In the case of a public utility, adequately maintained and rendering

efficient service to the public, to deduct for accrued depreciation according to the practice of some of our theorists, necessarily results in confiscation of investment. Mr. Humphreys.

Certain appraisers of reputation have taken the ground that if, for instance, railroad ties have an effective life of 10 years, and one-tenth of the total number is renewed each year, there is no need for a depreciation reserve, but the value of these ties as a whole should be depreciated 50 per cent. Nothing, according to the writer's way of thinking, could be more fallacious. The property, as far as this item is concerned, is thus maintained at maximum efficiency. What more could be done? Why then should one-half of this portion of the investment be confiscated? If so ordered, then we should be permitted to include a like amount as one of the overhead charges. If such an elimination is a necessary feature of railroad operation, then this is a legitimate item of cost.

Those who have not studied this subject carefully seem to think that because we should expect to allow, if we were selling, and should expect to claim, if we were buying, an allowance to be deducted from the purchase price to cover estimated accrued depreciation, therefore depreciation should be deducted in an appraisal for rate-making. On the contrary, the reason for such an allowance for depreciation in case of purchase and sale, furnishes the reason for not deducting it from an appraisal of cost new; for this indicates that there is the assumption on the part of the purchaser of a liability resting on the present owner. This is well set out in Mr. Wilgus' concluding paragraph.

This feature of depreciation the writer has treated at length in a recent paper.*

In conclusion, the writer desires to state that we, the Engineers of the United States, must appreciate that on us rests the grave responsibility of protecting the innocent investor, the widow and orphan, from spoliation at the hands of honest and dishonest interpreters of the laws of our country—Federal and State.

J. H. Gandolfo, Assoc. M. Am. Soc. C. E. (by letter).—The problem of obtaining the physical valuation of the railroads of the United States is probably one of the most important relating to public service corporations and properties that has ever been undertaken; and the question of rate-making, whether founded on the results obtained from physical valuation or not, is dependent on so many questions, both economic and financial, as to make it very difficult to discuss the matter within the limits of a single article. Mr. Gandolfo.

To investigate this matter of valuation and rate-making properly, it is necessary to study the historical development of the railroads from

* "Depreciation: Estimated and Actual," read before the Institution of Gas Engineers of Great Britain.

Mr. Gandolfo. their beginning, and then to analyze the entire question according to the principles of economics. This necessitates looking at the problem in a way very different from the generally accepted financial viewpoint.

Mr. Wilgus attempts to show that, from every point of view, the only just and equitable valuation to be placed on railroads for rate-making purposes, is that of replacement value new; but are his premises correct in this argument, and is replacement value new the logical figure to be used for this purpose? Would such a basis of calculation be just and equitable to the railroads, as well as to those who must pay the rates?

When a physical valuation is undertaken, no matter for what purpose, there is no doubt that the replacement value new should be estimated, taking the average cost of materials and labor for the five previous years, as is usually done; but the actual cost to date should also be determined, by reference to records which may be available, or, if not, by reconstructing all conditions as they existed at the time of the building of the road. The depreciation of the various elements entering into such a property should also be estimated at the same time. These three items can thus be determined simultaneously at very little more cost than that necessary to obtain any one of them alone, and at infinitely less cost than would be necessary to obtain each one separately. In fact, it may be said that for all practical purposes it is necessary to obtain all three of these items as a basis for study and comparison.

Referring to the sale value of the various elements entering into the construction of a railroad, such valuation is productive of no results except, perhaps, as a very poor, makeshift basis for taxation. If quantities of materials such as go to make up a railroad, were suddenly thrown on the market, it would in most cases at once depress the second-hand price of each, and thus create a price far below even the ordinary sale value. On the other hand, even taking the market sale value for estimating purposes would, as Mr. Wilgus points out, by no means give any idea whatever as to the actual values or actual costs of railroad property. As for the sale value of a railroad as a whole, such a quantity may be said not to exist, as there are no buyers for such properties in the open market. When such a property has been offered for sale, it has been bought in by a syndicate composed more or less of interested parties, and at its own price.

On page 205, the author states that it would be a very difficult matter to get any idea of the original cost of the railroads on account of the non-existence of records on the subject, and gives this lack of records as an argument as to why original cost to date should not be obtained and used. The mere difficulty of arriving at a result

is surely no excuse for not doing the work. It is only a matter of more time and patience, to go back and, with figures based on known prices for labor and materials of the period, reconstruct a road built fifty or more years ago, than it is to reconstruct the road under present-day conditions. Mr. Gandolfo.

Also, at various places, the author mentions different items of expense in the planning and construction of a railroad, which he seems to fear might be omitted in a physical valuation. On page 206 he says: "Reconnaissances, preliminary surveys, and estimates of cost, revenue, and profits are needed * * *", and, on page 211, various construction items are referred to as matters which should not be overlooked. It is difficult to conceive that any one engaged in a valuation or appraisal of a railroad, except the merest tyro at the business, would fail to take cognizance of such items. The cost of all preliminary work, of whatever nature (including promoting), and the cost of all construction work, should be estimated, no matter for what purpose the valuation is being made. One might as well try to estimate the cost of concrete in place, and say the cost of the form work should not be taken into account.

When it comes to including in the physical valuation the cost of what Mr. Wilgus calls "the educational and development stage", however, the writer fails to see why such expenses should be estimated for this purpose. This matter is purely one of operation, and the obligations which it was necessary to issue in order to obtain working capital in the early stages of a railroad, should have been paid off from profits, and a fund kept for this purpose from accrued profits. On page 207 the author says, "under the most favorable auspices, it usually lasts for several years". If a railroad is properly run and properly managed, the educational and development stage never ceases. For instance, the training and education of employees for their various duties never end. The study of places where economies can be practiced is something which should be in the mind of every one connected with a railroad at all times. The attempt of the advertising department to induce more and more travel, both freight and passenger, to patronize a given road, is also a never-ending work. As far as "errors of design and construction, as developed by operation," are concerned, these should be paid for out of profits, if there is money to pay for the work, because there is practically no limit to which such changes can be carried. To-day, expensive tunnels, long cut-offs, great trestles, deep fills, and heavy bridges, are being constructed on various railroads, simply to correct just such errors of design and construction; and if such corrections and betterments are to be capitalized as new development, what security is left for the obligations already issued against the original and now abandoned work? Of

Mr. Gandolfo. course, it must also be taken into consideration that improvements are often made for the purpose of handling increasing traffic and steadily increasing weights and loads of rolling stock. In all such cases, the only thing to do is to take the difference in cost between the old work and the new (if the cost of this new work is greater), and charge it to physical valuation. To illustrate this by a concrete case, assume a bridge, the original cost of which, complete, was \$100 000. Now, assume that this bridge is replaced by one costing \$200 000, either to correct some error in original design, or to provide for more or heavier traffic. Such a structure must be included in the valuation at its cost of \$200 000, or \$100 000 added to the original valuation of the road; but by no means should the total amount of both structures, or \$300 000, be included in any valuation, or obligations issued against this latter amount, as has so often been done in the past. Thus, it can easily be seen that the engineer who attempted to include any such feature as this, of the educational and development stage, in a physical valuation, either for original cost to date, or replacement value new, would be confronted by a peculiar problem. He would not know where to begin, or where to leave off. It would be simply a matter of personal opinion as to what and how much to include to cover some arbitrary period.

Furthermore, in this connection, it is to be remembered that, like everything else, railroading has been a slow growth, and that it has not been necessary to organize forces from absolutely ignorant material to handle the complicated equipment and traffic of to-day. The transition from the small systems beginning in England in 1825, with a few miles of track, equipped with tiny cars and 8-ton locomotives, to the great transcontinental lines of to-day, with thousands of miles of track, cars with a capacity of 110 000 lb., and great Mallet compound locomotives, was not made in a single stride. It was a slow development, and the operating force was gradually trained and organized to meet the conditions as they arose. And, further, if it could be imagined that a great railroad system was to be created new, to-day, with miles of track, modern equipment, and great terminals, even then, it would not be necessary to organize a new force from raw material. All the men holding positions of any moment would be obtained from other railroads. A few years ago, the writer was connected with a new railroad while the operating force was being organized, and all the men in positions of any importance, including such as general superintendent, shop superintendent, heads of all operating divisions, etc., and, also, in many cases, the subordinates, were obtained from other roads.

In regard to cost of reproduction less depreciation, it does not seem as if any allowance should be made for depreciation, either in

Mr. Gandolfo.

an original cost-to-date valuation, or cost of reproduction new, assuming, of course, that the road has been kept in first-class condition; that an amortization fund has been provided for, to meet all maturing obligations; and that some provision has also been made for obsolescence. If such items have not been fully provided for, then the question of depreciation may become a very important one, and must be given very careful consideration, with special attention to the object for which the valuation is being made. This can be made clear by referring to the coal pocket mentioned by the author on page 208. If a physical valuation had been made of this property the year before it was to be renewed, and if this item had been included at its full value of $600 000, there must have been one of two provisions made, as follows: Either an amortization fund must have been created, by which all stock, bonds, or other obligations, representing the full value of the coal pocket, will be retired at the end of the next year, so that new obligations can be issued to pay for the new work; or, if the obligations against the full value of the coal pocket are not to be paid off, there must be some fund, which, at the end of the next year, will amount to $600 000 in cash, so that the new coal pocket can be paid for without issuing any further obligations. Otherwise, if no such provisions have been made, the coal pocket must be included in the valuation simply at its present value.

This case illustrates another method which may be used to estimate depreciation, and that is, when the physical valuation is being made, to estimate the amount, in a lump sum, which it would take to put each item in first-class condition for the uses for which it was intended, and then to deduct this amount from the actual cost or replacement cost, whichever plan is being followed. This method of estimating depreciation has its advantages in that it eliminates assumptions and estimates, as to the probable life of a structure; but, on the other hand, it has its disadvantages, inasmuch as it only applies strictly to present-day values, and takes no account of the fact that depreciation is apt to be more rapid in the later years of the life of any structure. This is one of the reasons why the writer stated in his opening paragraphs, that values for depreciation should be determined for purposes of comparison and study.

On page 209, in discussing land values in regard to "original cost" valuation, Mr. Wilgus says, "it ignores the increment that is enjoyed by all other property owners through increase in the population and prosperity of the country"; but, in this connection, Mr. Wilgus seems to ignore the following fact. A railroad, or, in fact, any other public service corporation, does not occupy the same position, relatively to the public, or to the State, as a private citizen. A corporation has no being and no existence until created by the grant-

Mr. Gandolfo. ing of its charter by the State, which charter defines in just what direction the corporation is to exercise its functions. A railroad corporation is thus granted rights, privileges, and immunities by the State, which are not accorded to the individual. It is a fundamental axiom of both law and economics that something cannot be obtained for nothing, and thus, in return for these grants, the railroad must give up some things to the State, which the latter cannot demand from the individual. In regard to this question of land, it must be remembered that, especially in the early days of railroading in the United States, large grants of land were made to these corporations by the State, either without any compensation whatever, or at a merely nominal figure. It is not equitable that the present generation, having lost this land through no fault of their own, should now in addition be indirectly taxed for what their ancestors gave away without compensation.

In the following paragraphs the writer wishes to point out some additional anomalies and contradictions which would occur if the replacement value new was used as a basis for rate-making purposes.

According to an old print, the great Tring cutting, made in 1837, on the London and North Western Railway, was excavated by hand, and the spoil was removed in hand-barrows, guided by men, and pulled up inclines on the sides of the cutting by ropes passing over pulleys and worked by horse-power. In estimating such a piece of work for replacement value new, should these conditions be duplicated, only with present-day prices for labor and material, or should modern steam-shovel conditions prevail? It seems to the writer that, in a case like this, the railroad might find that, in spite of high labor and material prices, the cost of such a work would be much less than the original figure, and thus be an injustice to the company.

Referring to the temporary trestle work mentioned by Mr. Wilgus on page 211, on many of the early roads in the United States such structures were built of timber obtained along the line. It surely would not be just to estimate a value for such a structure based on present-day figures for the labor and materials entering into it.

About seven years ago, the cost of a certain class of steelwork, erected in place, was 4.07 cents per lb. Since that time this price has not been reached, but the same class of work has been done as low as 2.87 cents per lb., or a difference of 29½ per cent. It would not be just to say to the railroad which had paid the higher price, "Here, you must reduce your capital, because the work can now be done cheaper". This money was honestly invested, and it would be unjust to wipe out a part of such invested capital.

Another objection against replacement value new for rate-making purposes, is that it would be a constantly varying quantity, whereas

original cost to date would only have to be corrected for such additions and betterments as were added from time to time. Mr. Gandolfo.

In conclusion, it seems to the writer that for rate-making purposes, the total cost of the work to date, is the figure to be obtained. This figure represents the actual amount of capital invested in the enterprise. It may be argued that some railroads have depreciated, instead of appreciated, in value, and that no rate could be fixed, which would give a fair return on the investment. This is true, but in such a case the enterprise is not a success, the company is insolvent, and should be treated as such.

It may also be argued, as Mr. Wilgus indicates, that this method of valuation puts the older roads in a much more favorable position than those built at a later date. This is also true, but it was a question for the promoters and builders of these later roads to consider in their preliminary estimates, not for the State and the people to consider now.

T. Kennard Thomson, M. Am. Soc. C. E.—The Society, and indeed the whole country, owes Mr. Wilgus a vote of thanks for his very complete and valuable paper. It would be difficult to find a phase of the subject on which he has not touched. Mr. Thomson.

The valuation of railroads is, of course, one of the most far-reaching and important investigations ever undertaken by this or any other Government, and the results obtained by the present Commission will naturally be of inestimable value. It is safe to say, however, that, unless this work is done in harmony with, and with the hearty co-operation of, each railroad, the results will not be worth one-quarter of what they should be.

Although the speaker is a strong believer in the benefits which will accrue from the present Government investigation, he thinks that the ultimate object is the "intrinsic value" of the railroads; that is, the real commercial value—not an artificial assumption.

If desirous of buying anything, one must pay what the seller can be persuaded to take, and he, naturally, will not sell if he thinks he can get a better price elsewhere. A seller likes to think that he is getting back all that was spent on his property plus interest, either simple or compound, but he would probably sell at once for a small fraction of the cost, if satisfied that the proceeds could be invested so as to net him a larger or safer income.

The value of a railroad, like that of any other property, must fluctuate enormously from time to time, due to changed conditions or changed management; and these fluctuations may have very little relation to the original cost of the property.

In buying a fine diamond, does the purchaser inquire what was spent in mining it? If two young men take the same course at

Mr. Thomson.

Harvard, one at a cost of a few hundred dollars a year—which he earns as he goes—and the other at a cost of many thousands of dollars, will not the first almost invariably be able to sell his services for a higher rate? If these two boys were to invest the same amount of money in houses, one might build or buy a number of houses which he could sell for a big profit; the other might put all his money in a single house and not be able to sell it for one-quarter of its original cost. Two men might start a grocery business, under exactly the same conditions, but with entirely different results, as all know, and so on, *ad infinitum.* Why, then, should a railroad alone be forced to put false or fictitious values on its property—for sale, rate-making, or taxation, etc.—instead of its real value at that time?

Suppose a railroad is only a couple of hundred miles long. It may be in first-class condition in every respect, but if it has not a working arrangement with other roads at each end, whereby it can obtain its share of freight, its earning capacity will not be enough to pay operating expenses; and to-morrow a new manager may "get the business" and pay the stockholders a handsome profit. This has been done over and over again. In one case a young engineer, who saw a western road which was "run down", told the owners what he could do if they paid him a percentage of the profits; his proposition was accepted, and this made him a multi-millionaire. How would any basis of actual cost, or cost of reproduction, be applied to these cases?

Mr. Wilgus very truthfully states that it is impossible to ascertain the real cost of a railroad already built. He also states that it has never been possible to predict the actual cost of a road; "cost of reproduction" would come in the same class.

Among other things which have cost the railroads much and would be hard to find are the items of ballasting mentioned by Mr. Wilgus, who states that 24 in. of ballast are needed. In many cases the depth of the ballast is actually more than 12 ft.

Cost of litigation, and other obstructions by property owners, are enormously expensive, not only directly, but also in the brain energy required to overcome them, which might have been spent on the construction or operation of the road. For instance, the Chesapeake and Ohio Railroad, being unable to obtain from an old Virginian permission to use part of his property, took possession. The owner removed the tracks and buried the corpse of a woman there; the railroad company dug up the body and buried it 150 miles away; the owner found the body, brought it back, and again buried it on the "right of way", this time embedding it in concrete. As the concrete was very hard, and the railroad company did not like to use dynamite, it simply raised the grade of the track, and allowed the body to remain in peace under the rails.

Without the co-operation of the railroads, an investigator might easily overlook the old New York Central Railroad line through Kingsbridge, New York City, and estimate the Marble Hill cut-off at a fraction of its cost. In the West a railroad tunnel which had been closed three times by land slides was abandoned for a temporary line with a very sharp curve, and years afterward was rebuilt in a different location. Mr. Thomson.

But why continue when every one knows that the exact cost of an old or to-be-built railroad can only be ascertained approximately?

Mr. Crehore's suggestion, that the railroads put a valuation on their own property, has much merit, and reminds one of the method used in Germany for many years, the speaker believes, successfully, whereby the owner of a house gives the valuation of his property, and this is used by the Government for purposes of taxation and fire insurance.

CHARLES S. CHURCHILL, M. AM. SOC. C. E.—In the speaker's opinion, Mr. Wilgus should be thanked for having brought out his points in a very clear form, these points being recognized as generally correct. Within a few weeks after the issuance of the paper the Government officials made some very important statements: First, that the valuation of properties of common carriers in compliance with the Act, Section 19-a, is an original proposition; second, that it is a continuing one; and, third, that the physical elements must be compiled or estimated in accordance with the Interstate Commerce Rules of Accounts, as stated in the Act. Mr. Churchill.

Under the first statement, that the valuation of properties is an original proposition, it appears probable that no value which has heretofore been made will fully meet the requirements of the Act. Under the second statement, that the requirement is a continuing one, it becomes extremely important that accurate records shall be kept of the cost of all work, in accordance with the Interstate Commerce accounts. This statement also has led to plans being formulated by Government officials for preparing their files to cover 100 years. The third statement, that all records and estimates shall accord with the Interstate Commerce accounts, is one of the most important features of the whole Act, because this simple requirement answers many of the points raised in the written discussions on this subject, especially for the reason that the Interstate Commerce accounts are quite clear. Therefore, it is thought very important that the law should be studied very carefully, as it is a good one in many respects.

Many progressive railroad properties double themselves within 20 years; therefore, suppose one makes a valuation now, 20 years hence very little trace of the items reviewed at this date will be found, because the properties are changing and building up constantly.

Mr. Churchill.

The question has been asked, "What has the public gained in existing railroad properties"? Recently, some records of railroad construction between 1850 and 1856 have been found, which show that a railroad was being built across one of the Colonial States, and that within 6 years—before it was entirely completed—the actual returns in taxable values were doubled in each of the counties through which the railroad passed. This old record shows where both the individual land owner, and also the communities, counties, and State have gained from the fact that certain individuals combined in constructing railroad properties. This is one kind of return out of many others which have come to every community and State in which railroads exist.

Attention is called to the point in the law, that the valuation asked for is not confined altogether to physical features; also, that the law specifically calls for the cost of the property to date; in other words, that the investment in a property must be determined as closely as practicable, as being an important element. If, therefore, a railroad has built a property within recent years, or has bought one at an earlier date, and has made considerable additions thereto since the date of acquirement, the original cost plus the additions must be determined. In most instances records of expenditures have been carefully kept, and usually there are three parties to these records, namely, the railway company, the contractor, and the engineer. The amounts paid, therefore, show on their face the true cost of the work when built.

Finally, attention is called to the recent decision of the Supreme Court in the Minnesota Rate Case, wherein a favorable decision was given in one case, and, in that case, the original investment was protected.

In conclusion, it seems important to draw attention to the greater likelihood of overlooking items of cost after the structure or railroad has been completed than in making proper allowance for contingencies before the work is undertaken; and that these items of cost, which are so likely to be overlooked in works already completed, should be searched for in great detail, so that the application of percentages to cover past contingencies may be avoided as far as possible.

Mr. Coombs.

R. D. Coombs, M. Am. Soc. C. E. (by letter).—It would appear to be necessary to have a more general acceptance of what is meant by "cost" and "value": Whether the "cost" of construction is its actual cost, what it should have cost under actual conditions and average good management, or what it should have cost under average conditions and average good management; and whether the value new corresponds with any or none of these.

Assuming that the railroad's actual expenditures could be determined, they would in fact represent the cost, whether that cost

was unusually low, or unusually high, unless it is accepted that deductions should be made for bad luck, ignorance, or dishonesty. Mr. Coombs.

If it is a fact that, owing to working conditions, weather, accidents, high wages, and relatively expensive material, a certain work cost the railroad an amount greatly in excess of its probable cost under average conditions and efficient management, should the actual cost be accepted as its value new?

If the necessity of maintaining service compels expensive construction, should the excess cost over that of average conditions remain a part of the cost of the work, and would that cost be accepted as the value new?

If the improved methods of construction now available would decrease the cost of new work below the amount actually expended, should such methods be used in estimating the value new?

If the original contour and the topographical conditions along the line are assumed to be restored in the cost of reproduction new, a fair estimate, in some cases at least, would require us to assume the surrounding country restored and to make some allowance for working under such conditions.

Until those discussing this matter agree on the foregoing points, there will naturally be no agreement on further extensions of the subject.

That the actual cost would be difficult to determine does not appeal to the writer as a logical reason for discarding it altogether. In many cases the cost of reproduction new might be used as a "side light" on the actual cost.

It must be admitted, however, that the actual book records are not absolute cost records. In fact, the writer does not believe that the accounts of any railroad, and of but few contractors, would show the complete expenditures for a given construction.

Referring to the acceptance of one basic principle or another, and to the deduction or inclusion of depreciation, depending on the purpose of the valuation, it would appear:

First.—That if the directors have set aside a depreciation fund, that fund plus the physical property represents accurately the full physical value of the property, and may be properly used as the physical value for any purpose.

Second.—If such a fund has not been established, the physical value is represented by the actual physical property, and is less than 100% of its book value.

Third.—As the present stockholders are not necessarily the original stockholders, some of them, under the last assumption, are innocent purchasers of stock which does not represent full value, in so far as the physical property is concerned.

Mr. Coombs.

Fourth.—The physical valuation of a railroad is its valuation as a railroad in its present location, and, from an engineering standpoint, the value should be the same either for sale, taxation, or rate-making.

Fifth.—If taxes are too high or too low, change the percentage; if freight rates are too high or too low, change the rates.

Mr. Ingersoll.

COLIN M. INGERSOLL, M. AM. SOC. C. E. (by letter).—To railroad engineers who have advanced in their profession, and have been through the construction period from beginning to end, this paper will most certainly appeal, for it describes in detail the very steps taken in building a railroad.

As yet, the physical valuation of railroads is in its infancy, and no definite method has been determined for making such valuation; but Mr. Wilgus has done a great service to the Profession in publishing his paper, and this will be proven when the final method of valuation is determined by the Government.

The method to be used in arriving at the valuation depends somewhat on what use is to be made of it. If it is for a quick transfer by sale, it would seem that the property should be turned over on a reproduction value, less depreciation; but if the property is kept up in a substantial manner, it would seem to the writer that the cost of reproduction new is the method which comes nearest of any that has yet been advanced to putting all roads on the same footing. The original-cost-to-date method of valuing would not seem to the writer to be fair for all, for until very recently the railroad companies were rather slack in keeping accurate costs of work. Take a railroad built in the Sixties or Seventies, the books of which have been kept up (and the writer doubts if there are very many such roads); the books would show the money that had been put into the railroad, but without any allowance for the enhanced value of the property. Perhaps the road adjoining has kept no books, and, consequently, in order to arrive at the present value, some method of reproductive value must be used.

In the first instance one cannot, by any arbitrary rule, arrive at the present-day values unless one gets at the cost of reproduction; and if this is done, the original cost is of use as a side light. Then, again, rarely in "original costs" are the whole costs shown. In construction work contractors have often received extra compensation, either by agreement or through legal process, which does not appear in the book cost of the work. Book costs show the cost of the property, but rarely include all the costs, such as engineering, legal fees, commissioners' fees, interest on money during construction, and operating losses, which really are a part of the cost of the property. In many instances land has been given and contributions have been

made, for establishing stations, side-tracks, etc., in order to induce the company to build. It would seem to the writer as if they were just as much a part of the road that should be allowed to earn interest as that which was paid for. It is taxed, and can be sold and credited to the company. In many instances the purchase price of land is more than the value of the adjoining land, and rightly so. Those who have had to do with the purchasing of right of way know that one cannot go diagonally through a piece of farm land, say 5 acres, take out 2 acres, and leave the remainder of the same value per acre. For that very reason an extra price has to be paid, whether it is called an increment, damages, or an inducement to sell. It is there, and is a part of the cost of the property. Mr. Ingersoll.

If for any reason the records of the purchase of this piece were destroyed, it would not seem to be fair that it should be valued on the basis of the value of the adjoining property. It is true that railroads can condemn, but, with small pieces of land, it is generally cheaper to purchase at a higher price than to go through condemnation proceedings, pay for commissions, lawyers, engineers, and witnesses, which, if the property is not expensive, amounts to a big percentage of the cost. Take the same case of 5 acres of land, at, say, $10 per acre. The owner for some reason, often for gain, refuses to sell. Has it been the experience of any one who has purchased land for right of way that the railroad company can get the 2 acres of land needed for $20 by condemnation? No; the lawyer, the commission, the witnesses, the engineering, etc., would cost more than twice that amount, and some method must be found to include these legitimate expenses in the value of the land. Otherwise, the railroads will have to put in capital on which no return in the way of dividends can be paid. This certainly would not seem to be fair to the investor.

The writer believes that it is proper to charge property with its share of the engineering and legal expenses, and contingencies, for the very good reasons set forth by Mr. Wilgus.

For rate-making purposes it is not believed that depreciation should be deducted from cost of reproduction. Depreciation is an element of operating costs and an obligation of the stockholders.

If a railroad has been allowed to run down while dividends have been paid, then the stockholders should forego dividends, and the earnings should be put into the property until it is brought up to standard.

Arthur M. Waitt, Esq. (by letter).—The writer has read this able paper with great interest, as it is based on large practical experience, and deals in a broad and comprehensive manner with a subject which is of vital importance both to the railroads and the general public. Mr. Waitt.

Mr. Waitt. Probably few, if any, men have given deeper or more conscientious thought to the subject, or have had such an extensive practical experience to enable them to deal with the matter as fairly and comprehensively, as Mr. Wilgus.

It is the writer's firm conviction that in determining the physical value of railroad properties for purposes of rate-making, in justice and equity, only one basis can be used, namely, that which considers the actual capital required to reproduce the conditions and facilities found necessary by the railroads to produce their revenue, and he fully agrees with Mr. Wilgus that for rate-making purposes depreciation should not be deducted.

An intimate relation with the shop equipment and rolling stock of both American and European railroads for a long period has caused the writer to study especially the treatment of these important elements in the total valuation of railroad properties.

Oftentimes, in his practical experience, the question has arisen as to whether comparisons of the values of equipment and rolling stock taken at different periods, several years apart, would show an appreciation or a depreciation. In every instance, a careful analysis of the facts and figures, ignoring new equipment charged to the "improvement" or "capital" accounts, has shown no net appreciation in values, due to the fact that new tools and rolling stock purchased to replace old ones were invariably heavier and more valuable than the worn out or obsolete equipment. It would be true only in a few exceptional cases that, in valuations made 5 years apart, there would be an actual depreciation in total values of unincreased equipment.

If physical depreciation were deducted from cost to reproduce new, figures would be obtained which would not fairly represent the capital involved to provide the facilities and operating conditions on the railroads, for which adequate rates for transportation should be allowed.

A fair valuation of equipment or rolling stock, or, in fact, of any of the elements composing the railroad's total value, cannot be made, except by a reasonable personal examination by qualified experts in the different fields, and it cannot be done equitably by arbitrary or set rules applied regardless of local conditions.

In a valuation of the equipment or rolling stock of a railroad to determine its purchasable value at any given time, different principles would apply, and in such cases the cost of reproduction new, less existing depreciation, would be the correct measure of value. In a valuation for this purpose, no set prices and rules, applicable to all cases, can be established; the prices and percentages must be established after an examination of a sufficient portion of each class of equipment to enable an expert to determine the comparative initial values and the quality or standard of maintenance, this latter to be used in the case of each class of equipment or rolling stock.

It would be manifestly unfair to value by the same standards and figures the property of two railroads, one of which constantly purchases new locomotives, cars, machinery, and tools of the highest grade, having all the best features for obtaining high efficiency in service and longevity of equipment, and on which, by the wise expenditure of money, the equipment is maintained in the best condition for service, while the other road purchases cheap equipment and expends as little as possible in maintenance. Situations approaching each of these cases will be found, and the writer maintains that they can only be handled equitably by qualified expert judgment after personal inspection. Mr. Waitt.

No more important facts can be urged for consideration and correspondingly wise action than those which are made prominent in Mr. Wilgus' paper, but in closing the writer wishes again to emphasize two of them which, to his mind, are the most important, namely:

1.—The cost of reproduction new without depreciation should be taken as the only fair and true measure of the physical valuation of railroads for purposes of rate regulation.

2.—Expert skill and experience must be enlisted in order to make a proper estimate of the true value of railroad properties.

Stevenson Taylor, Esq. (by letter).—The general principles involved in covering methods of determining valuations of railroads, with the attendant matters of bookkeeping, establishment of costs, and the important subject of depreciation, have been considered by the author with admirable thoroughness, and the writer has no good reason for differing from his conclusions. Mr. Taylor.

If we hope to encourage "men fitted by experience, acquaintanceship, resourcefulness, courage, and tact," as well as investors large and small, so that the building, extension, and upkeep of railroads may proceed further to advance the interests of the whole country, we must deal justly with this broad question of public utility and with those who are and who may become directly interested therein.

The author has pointed the way. There may be differences as to minor details, but his paper covers the subject in a masterly manner and with fairness and justice to all concerned, including the general public.

F. C. Hand, M. Am. Soc. C. E. (by letter).—The valuation of the railroad properties of this country under the recent Act of Congress is indeed a Herculean task, probably the greatest that has ever been undertaken by our Government. The results of this work will be far-reaching, in whatever light they may be considered, whether for purposes of taxation, rate-making, ultimate Government ownership, or for the purpose of regulating stock and bond issues, as is now the case in Texas. Mr. Hand.

Mr. Hand. The writer, however, cannot agree with the author that the ultimate valuation shall depend on the purpose for which it is to be used. There can be but one measure of actual value, as the Courts have said that the value of a property depends on the use to which it is put, and railroad property can certainly only be used for railroad purposes. If a valuation is placed on the property for rate-making purposes, where is the injustice in requiring taxes to be paid on the same valuation? Taxes are only one item of expense in the operation and maintenance of a railroad, and are taken into the accounts as such and are considered in fixing rates.

The sale-value method would hardly seem to be worth considering in this connection, as so many questions of franchises, connections, traffic facilities, outstanding obligations, and many purely intangible elements of value, that might and usually do have weight with the purchaser, would enter into the transaction as probably to modify the actual physical value very materially.

Should the Government ever acquire the roads, the owners would insist on being paid the value to them at the time of purchase, and would probably also insist on capitalization value in most cases. In that event, the valuation to be made by the Interstate Commerce Commission would be most valuable, as the relations between actual values and capitalization will be clearly defined in every instance.

The Act of Congress provides that Original Cost to Date shall be determined as one of the alternative plans, and, as Mr. Wilgus truly says, this will be a difficult undertaking. Simply because it is difficult does not by any means make it impossible. It is probably true that many of the old records are very incomplete, and also that many of them are missing, but all engineers know that in almost any appraisement there are some missing and incomplete records, and that it is necessary to go back to the period of construction for cost data, and that the greatest care is also necessary to estimate properly all conditions existent at the time when the work was actually done. This will be at times extremely difficult, but with care it should not be impossible.

The writer remembers a case in point: Some years ago a line of railroad was built across a marsh for about 3 000 ft. There was no pile-driver available, and the line was cribbed with timbers cut from and adjoining the right of way, a very expensive operation. As soon as the track was laid a top-driver was obtained and a pile trestle was driven. A few years later the marsh was drained and the entire trestle was filled with steam shovel, and now there is no indication, except the absence of borrow-pits, which would put an experienced engineer on inquiry, to show but what the entire fill might not have been put in at the time the road was originally built. Possibly the original records in this case are available; if they are not, careful in-

quiry and investigation would detect the original conditions, and the original cost could be arrived at pretty accurately. Mr. Hand.

Original Cost to Date is evidently intended by the Act to show the amount of capital actually invested in the properties, and if all the items of original cost are included the result should be very satisfactory.

The author's ideas on Cost of Reproduction New are extremely lucid, and would probably be accepted by most engineers of experience as giving a good definition of the various steps, except possibly the "educational and development stage," which is not a closed chapter when the road becomes a self-sustaining or dividend-paying proposition. This system of education and development is never completed, but the cost, of course, is a part of operating expenses.

The method of valuation by Cost of Reproduction, Less Depreciation, which is provided for by the Act, is probably the one of the three methods which will be productive of the most discussion, and the one on which the greatest variance of views will appear, except possibly on the question of estimating proper land values. This extreme variance of opinion appears to the writer to be chargeable to the effort to establish a fixed basis or standard by which depreciation shall be computed. It is of course beyond dispute that nearly all the essential parts of a railroad are constantly wearing out, and consequently depreciating, but constant repairs and renewals are being made, paid for out of operating expenses, so that a first-class railroad may at all times be said to be nearly 100% perfect, from the standpoint of efficiency. In such a case, depreciation is surely negligible, as an amortization or surplus fund is being constantly set aside to provide for renewals and also for obsolescense. This fund, by whatever name it may be called, is provided out of earnings, that is, it is being provided by the public, and its reinvestment should not be taken into capital account.

Unfortunately, not all roads have handled this matter in this manner. Some of them have paid to their stockholders, in dividends or otherwise, the money which should have been set aside, and have floated another bond issue when extensive renewals or improvements became necessary, and other roads have never been able, from one cause or another, to earn enough money to set aside anything for these purposes.

These are the actual conditions as they exist on our different roads, and the writer can see no way, except by a careful and painstaking examination of each particular case by itself, to arrive at a fair estimate of depreciation. No general formula can be adopted which will be fair in all cases.

The question of land values is also one on which there are many varying views. The author says:

"The 'original cost' measure of land values is believed to be unfair, for two reasons: It ignores the increment that is enjoyed by all other property owners through increase in the population and prosperity of the

Mr. Hand. country; and it would lead to the inconsistency of low original values on lines unfortunate enough to have preserved their land records, and high costs on adjacent lines where the absence of records would make imperative the use of present-day values."

The writer is unable to see anything really unfair in this, as under the provisions of the Act both the Original Cost and Cost of Reproduction New are to be ascertained. No increment could be claimed under the first, as the purpose is to ascertain the original cost only; and, in case the company's records are defective, a reference to county records will generally give the desired information. In the second case, the present-day values can be readily found, although there are many different plans suggested for arriving at this. The writer believes that this too should be the subject of a careful painstaking investigation in each individual case, and that no rule can be fixed which will be at all fair to both the railroads and the public. The right of way through each tract of land should be considered as a separate unit, and the matters of severance, plottage, and other damages, should be considered as they affect each tract. No uniform percentage can be used which will reflect actual values accurately, for perfectly obvious reasons. The writer has known of many instances where rights of way were obtained through comparatively large tracts when only actual acreage values were asked. The lands were not badly cut up; cattle passes or overflow waterways gave ready passage from one side to the other, and no damages beyond the acreage value could be shown. On the adjoining tract, however, the situation might be quite different, but simply because damages were caused in one case in a sum perhaps more than equal to the value of the land, is no reason why a percentage should be added in the other.

In this paper the author has not considered the capitalization of the railroads as a factor in ascertaining values, but the writer feels constrained to add a few words on this phase of the subject, as he believes it is a very live question and one that will be brought to the attention of the Valuation Division many times before this work is complete. In fact, considerable stress was laid on this feature in many of the discussions in Congress during the pendency of this Act and in the discussion incident to the passage of the appropriation for beginning the work.

The pertinence of a discussion of this feature will be apparent in the event that, as a result of this Act, an attempt should be made to regulate the issues of stocks and bonds, or should a proposition for Government ownership be seriously considered.

There is a pretty widespread impression that there is an enormous quantity of water in railroad securities, although this is stoutly denied by the railroads and by such statistical authorities as Mr. Slason Thompson.

Mr. Hand.

Mr. Thompson presents an imposing array of figures to show that the railroads of the country, taken as a whole, could hardly be reproduced for the amount of their outstanding stocks and bonds, and then he goes on and shows, from these figures, that the money invested in railroad securities is only earning a very moderate rate of interest.

This would appear to settle the question, but does it? Let us inquire as to the source of these stocks and bonds.

Many of our roads were financed and built on what a noted captain of industry characterized as the "package system".

A corporation was organized with a capital of say $1 000 000 in common stock, and $1 000 000 in bonds was immediately issued. A lot of preferred stock was also issued in some instances. These were sold to investors or to a syndicate at the best price obtainable, that is, the bonds were sold, generally below par, and a bonus of stock was given with each bond subscription. This was the "package".

The road was built from the proceeds of the bonds, the remainder of the stock being retained by the promoters. We now have a road which cost not more than $1 000 000 and even less, if less than par was realized on the bonds, but which is capitalized at $2 000 000 or more in stock and bonds. We will assume that this occurred twenty or thirty years ago. The road since that time has been ably managed, and sufficient money has been saved from earnings to keep the road in good repair, and in addition make continual improvements, such as ballasting the track, replacing wooden bridges with steel and concrete structures, buying new and heavier locomotives and modern equipment of all kinds, until now the road is actually worth the amount of its capitalization. Consequently, the stockholders insist that there is no water in the capitalization, as the road could not be duplicated for any less than the amount of its outstanding securities, even if it could be done for that, on account of present higher prices. But, whose money has made this present value? Has any one put in anything since the original construction of the road, except that which the public has paid in rates? It does not need a diagram to demonstrate that one-half at least of the capitalization is water, or is, at any rate, the profit made by the stockholders who originally put in nothing.

It will be urged that the promoters were entitled to a good profit, and that they and their successors are entitled to this increment on account of their able and efficient management, and to a certain extent this is true. The fact remains, however, that if a valuation is made having regard to the original investment, some one has made quite a lot of money at the expense of the public.

This particular state of affairs, of course, did not occur in all cases, and perhaps not even in a majority of them, but it serves to show the fallacy of the position that because the present value of the roads is

Mr. Hand. equal to their capitalization, if it is, that there is no water in such securities.

When the valuation of the Interstate Commerce Commission is complete we will have a much better idea where we stand in all these matters than we do now, and the results will undoubtedly be worth much more than their cost.

Mr. Norcross. P. H. NORCROSS, M. AM. SOC. C. E. (by letter).—Mr. Wilgus has presented a paper which deserves not only the approval of the Engineering Profession, but also that of the legal and commercial world. He has analyzed the fundamental principles of valuation of public utilities and presented them in such a clear-cut and concise form that he has left little opportunity for discussion. The writer feels safe in asserting that this paper will become a notable addition to that rapidly growing branch of engineering literature, "Valuation of Public Utilities".

The writer believes that "valuation" or "value" is one of the most misunderstood words in the English language. It is like a sharp-edged tool, which, when used by a skilled artisan, will perform the functions intended, but, when handled by one not competent and experienced, will become a menace and a danger.

The Matter of Value.—The work to be performed by the specially appointed Valuation Committee of the Interstate Commerce Commission, involves the determination of the value of the most important and largest branch of public utilities. A railroad is necessarily property of such a character that it has not what is generally known as "market value". It is not like a commodity which is frequently bought and sold on the market, the large number of sales thus forming a basis for determining that which is usually termed "market price". This condition does not usually exist with public utilities. The circumstances may be such that the utility being considered is not salable. Even if such a condition existed, it would not affect the question of "value".

"First and foremost the determination of the value of a public utility is a matter of judgment, and the accuracy of the determination depends upon the integrity, fairness, technical training, and ability, character, experience, and sound good sense of the man (or men) who makes it."*

The writer agrees that the practice of estimating "Cost of Reproduction New" is a prominent factor in determining the value of property. This principle has been adopted in the commercial world as a proper method for determining value. It is most important to have a clear and comprehensive understanding of this method, otherwise a correct conclusion cannot be reached.

* "In the Matter of Condemnation Proceedings Before a Condemnation Court," Des Moines, Iowa, *vs.* Des Moines Water Company; Brief by Guernsey, Parker and Miller.

Mr. Norcross.

The appraiser must place himself in the position of some one who is about to build a railroad, and must go through all the different processes from its conception to its completion and operation, so as to arrive at the proper value of the physical property, revenue, and other characteristics, which are all elements of value in the cost of the complete system.

One of the most important things involved in the estimate of the cost of reproduction is an inventory of the property to be reproduced, and the preparation of this inventory is naturally one of the most arduous tasks that will be undertaken by the Valuation Committee. This inventory, when completed, is the basis for estimate in the cost of reproducing the physical property, and should be made by honest, competent, intelligent, and experienced engineers.

As to the adoption of unit prices, these should be based on actual experience, covering construction work of similar nature under similar conditions, and should not be predicated on more arbitrary estimates.

What is to be ascertained is the value of the property to-day. Any attempt to estimate the cost of reproduction under conditions that existed, or might have existed, at the time the property was constructed, would most probably result in an estimate so inaccurate that it would not serve the purpose for which it was made, as it might be more or less than its present value.

As to whether depreciation should be taken into account depends entirely on the purpose for which the valuation is made. If we are seeking present value, then depreciation is material. If cost is what we are seeking, depreciation is absolutely immaterial. The very reason for taking depreciation into account to ascertain present value, however, requires that appreciation be given the same importance. The writer is aware that there are authorities who take an opposite view, but nevertheless, in his opinion, the foregoing is the correct method of determining present value.

At the present time, the work of the Valuation Committee is only in its incipiency and such a paper as Mr. Wilgus has written should be of inestimable value to the members of the Interstate Commerce Commission.

Mr. Harte.

Charles Rufus Harte, M. Am. Soc. C. E. (by letter).—This paper is a masterly consideration of the subject, and though specifically applied to railroad valuation is, in fundamental principles and in much detail, equally pertinent to other cases.

The author's professional standing and experience give great weight to his conclusions, but, as is almost necessarily the case in the earlier consideration of any question of moment, there are many who, viewing the situation from other angles, will find points of difference, particu-

Mr. Harte. larly in the matter of the treatment of depreciation, this independently of the series of consistent decisions by the U. S. Supreme Court.

Primarily, although many of the elements entering into it are difficult of exact determination, a valuation is the establishment of a fact, and as such it should vary only as the personal equations of the experts employed in different determinations are reflected in the variables; its intended use should have no consideration in establishing fundamental values, although it may determine what of these values shall make up the total to be obtained.

As to the method to be followed in determining this fact of the value, the "Sale Value" as defined by the author might more properly be termed the "Scrap Value," disregarding as it does not only the complex and moot factors arising from a "going" concern, but also the obvious fact that the assemblage of the parts into a complete but "dead" system is affected only at a very considerable cost over and above the price of the constituent materials as such.

Only those who have attempted the task can fully realize the utter hopelessness, in at least many instances, of determining with accuracy the "Original Cost to Date;" nor is the result obtained under the most favorable circumstances of necessity a correct valuation. "High Finance" methods on the one hand, whereby the directors of a railroad pay to themselves, as directors of a "Construction Company," contract prices far in excess of normal, or abnormally low prices on the other hand, to say nothing of items omitted from the record, will give an "Original Cost" which was not a true value at the time of construction, and may well be much more inaccurate at a later date, while appreciation or depreciation, both of which should have full consideration, are entirely ignored. The U. S. Supreme Court, in the Minnesota Rate Case decision, simply adds one more to the consistent chain of precedents when it says:

"It is clear that in ascertaining the present value we are not limited to the consideration of the amount of the actual investment. If that has been reckless or improvident, losses may be sustained which the community does not underwrite. As the company may not be protected in its actual investment if the value of its property be plainly less, so the making of a just return for the use of the property involves the recognition of its fair value if it be more than cost."

As to whether the reproduction cost shall be figured "New", or "Less depreciation" there can be but one answer: "Both"; for both are essential to a proper understanding of conditions. The author argues for "Reproduction new", but it would seem that in doing so he takes too much for granted. It is true, of course, that a sinking fund should amortize those wastes of substance which in practice are replaced only at considerable intervals, and after the loss has reached a critical value; and that regular maintenance should care

for every change that can be met as it occurs, but these are facts to be determined, and, except as it can be shown that the decrease in physical value due to such wastes actually, in the specific case considered, has been compensated by funding provisions, and such fund is made a part of the valuation, the physical value total must reflect the depreciation. Mr. Harte.

In the case of the coal pocket cited by the author, it will hardly be contended that, in its all but broken-down condition, the pocket has the same physical value as after the subsequent complete rebuilding —nor can there be doubt that, with a properly maintained and applied amortization fund, the total value of the railroad as a whole is the same at each time.

"If, however, a company fails to perform this plain duty" (to make provision out of earnings for replacement of waste) "and to exact sufficient returns to keep the investment unimpaired, whether this is the result of unwarranted dividends upon over issues of securities or omission to exact proper prices for the output, the fault is its own. When, therefore, a public regulation of its prices comes under question, the true value of the property then employed for the purpose of earning a return cannot be enhanced by a consideration of the errors in management which have been committed in the past."*

"It must be remembered that we are concerned with a charge of confiscation of property by the denial of a fair return for its use; and to determine the truth of the charge there is sought to be ascertained the present value of the property. The realization of the benefits of property must always depend in a large degree on the ability and sagacity of those who employ it, but the appraisement is an instrument of public service, as property, not of the skill of the users. And when particular physical items are estimated as worth so much new if in fact they be depreciated, this amount should be found and allowed for. If this is not done the physical valuation is manifestly incomplete. And it must be regarded as incomplete in this case."†

It is interesting to note that the March 1st, 1913, amendment to the "Act to Regulate Commerce" of February 4th, 1887, providing for the valuation of property of carriers subject to the act, requires the determination of all the above methods except the sale value, calling for "the original cost to date, the cost of reproduction new, the cost of reproduction less depreciation, and an analysis of the methods by which these several costs are obtained and the reason for their differences, if any".

Considering the details treated, the recognition of the initiatory and developmental expenses as legitimate elements of value will be assented to by all familiar with the facts, but detailed analysis of actual expenditures will undoubtedly be required to establish the fact on a legal basis.

* Knoxville *vs.* Knoxville Water Co., 212 U. S., 1, 10.

† Minnesota Rate Case decision.

Mr. Harte.

The point of many contingent items, difficult to foresee in the original construction or to recognize in an appraisal, is well taken. Quicksand, covered bogs, swelling clays, shattered ledges in fragments too large to handle with ordinary equipment and too small to blast except at high cost—the list could be carried out almost indefinitely—all are predetermined only by much more careful and expensive investigation than is practicable in the majority of cases, and are still more obscure after the work. The author notes the case of rock in a cut masked by earth washing over it, but here some clew may be had to earlier conditions. In the case of drained sections, however, quicksand or bog conditions which caused exceedingly heavy expense will often be completely removed after some time by the lowering of the water-table.

In the case of fills, it would seem difficult to sustain successfully an appreciation equivalent to the cost of compacting by puddling and rolling, as such a condition of density is not essential. There is, too, room for difference of opinion as to the extent to which it is proper to include costs of cleaning out cuts after operation has begun. With traffic of any moment, such work is extremely expensive, and though there can be no question as to the propriety of considering as a part of the value of the property the fair price of every yard removed, there is good argument against the inclusion of the excess due to work under regular operation, on the ground that such necessity arises from improper first construction.

The use, in determining interest, of "consistent" progress, is at least conservative. The condition of one or two critical points where unforeseen contingencies of one sort or another have delayed operation of the system until long after everything else is in readiness, is not at all unusual; and, under the regulations of to-day, a system ready for operation may be held idle for a considerable time pending the necessary authority. A case to the point is that of the Hampden Railroad, in Massachusetts, which, ready for operation on June 1st, 1913, after an expenditure said to have been practically \$4 500 000, at this writing, 6 months later, is still awaiting approval of its financing.

In the matter of land values, no one with any knowledge whatsoever of the facts can sustain the contention that a strip of land for right of way does not cost considerably more per unit of area than adjoining land purchased in normal parcels. Interference with the use of the portion cut off, where the property is divided; reduction of the remainder to undesirable or uneconomic size—these are takings of property rights in the portion left as real as if the land itself was taken and must be—and in condemnation awards invariably are—given proper compensation. No less effective in enhancing legitimate values is the advantage of the situation often taken by shrewd owners. It is true that a railroad has the right of eminent domain, but the exercise

of this right adds to the award the cost of the proceedings, and the delay—a case in Connecticut, begun in 1908, was not settled until the spring of 1913—often involves such expense in interest on the suspended construction as to make payment of an outrageous price much less expensive than to wait for the more reasonable Court award. Mr. Harte.

In the Minnesota Rate Case, the Court, it is true, refused to allow "the so-called railway value of the property", but that this was due to faulty presentation of the case is obvious in the opinion:

"But aside from this, it is impossible to assume, in making a judicial finding of what it would cost to acquire the property, that the company would be compelled to pay more than its fair market value."

And again:

"The Company would certainly have no grounds of complaint if it were allowed a value for these lands equal to the fair average market value of similar land in the vicinity, without additions by the use of multipliers or other use, to cover hypothetical outlays."

These quotations clearly show the failure, on the part of the railroads concerned, to develop legally the fact that "the fair average market value of similar land in the vicinity" is the value of land in right-of-way shape, and not that of land in normal parcels.

In this connection the engineer engaged in appraisal should bear strongly in mind what is too often forgotten or overlooked, not only by laymen, but by lawyers as well: The expression, "Blind Justice" as applied to the Courts is no mere figure of speech, but is a cold, hard fact. The lower Courts have very little leeway in considering any facts in a case, other than those legally presented, "judicial notice" relieving from proof only such facts as are of common knowledge beyond any question; and the higher Courts are bound absolutely to the records of the lower Court from which came the case.

The facts, therefore, in an appraisal—and for that matter in any engineering report—should be set out so that they not only can be understood, but that they cannot be misunderstood.

It has been argued that land occupied by a railroad is not entitled to any appreciation over its first cost, on the ground that such an appreciation is due to the railroad, and that if the latter were destroyed or removed the appreciation would be lost. This, however, is a question of fact. To a growing community with insufficient transportation facilities a railroad will almost invariably bring increased general values; but, except as it creates unusual manufacturing or other commercial facilities, it will depreciate its immediate vicinity; to an older settlement, having fair service, such railway improvements as additional trackage, increased terminal facilities, and the like, rarely add to general values, and almost invariably depreciate the territory affected.

Mr. Harte. In fact, the entire question of land and all other values harks back to the proposition that an appraisal is a statement of fact, depending on many variables; given an outline of the conditions, the use of averages will give a fair approximation to the total; but that appraisal which is to stand the test of the Courts—and that is the final test—must be based on, and must show beyond question and in detail, the elements of which the total is made.

Mr. Green. F. W. Green, Assoc. Am. Soc. C. E. (by letter).—As the subject of valuation occupies such a prominent place in public thought at the present time, a full discussion by the members of this Society will be most opportune. That correct principles may be expounded eventually, and erroneous conceptions convincingly exposed, is a consummation "devoutly to be wished."

On pages 307 and 308 occurs the statement:

"A railroad, or, in fact, any other public service corporation, does not occupy the same position, relatively to the public, or to the State, as a private citizen. A corporation has no being and no existence until created by the granting of its charter by the State, which charter defines in just what direction the corporation is to exercise its functions. A railroad corporation is thus granted rights, privileges, and immunities by the State, which are not accorded to the individual. It is a fundamental axiom of both law and economics that something cannot be obtained for nothing, and thus, in return for these grants, the railroad must give up some things to the State, which the latter cannot demand from the individual."

This reflects the popular attitude, but is it correct? It is said that the corporation originated in the days of the Roman Republic, when a vast undertaking, requiring a long period of time for its completion, necessitated the creation of "a body without decay, a mind without decline." The production of wealth flows from the application of capital and labor to the development of natural resources. Public wealth is measured by the magnitude of private wealth. The development of natural resources, therefore, must inure to the public benefit. Would our country be as well developed and as prosperous to-day if the organization of corporations had never been permitted? Could our present development have been attained by individuals or by co-partnerships?

A nation may be likened to a corporation—its life is derived from its Constitution. Does not such a nation gain "something for nothing" when it assumes its Governmental functions? But, we say, the Government, in return for what it receives, gives protection to its citizens, and therefore reciprocal benefits are enjoyed. How is it in the case of a railroad corporation? It derives its life from its charter. No sane Government would give life to a corporation unless it expected public benefits to flow therefrom. The "rights, privileges, and immunities" granted by the State to the corporation presumably refer to

the right of eminent domain. Does the State confer this right from motives of prodigal generosity, or *pro bono publico?* Does the corporation, in the enjoyment of it, get something for nothing, or does it pay a handsome price for condemned right of way? Any one with experience in condemnation suits knows the answer. Mr. Green.

Elsewhere in the discussions appear references to the acquirement of rights of way by public or private donation, and intimations that the people should now turn "Indian givers" by renouncing the acts of their forefathers. If such acquirements had been obtained by fraud, the ethics of such a procedure could hardly with justice be questioned; but, when these ancient transactions occurred, were the railway corporations the only beneficiaries? Does the construction of a railway through an undeveloped country produce any increment in land values? Was the value of the land acquired for right of way, before the construction of the railway, more than a small fraction of the increase in land values enjoyed by the owners after its construction? Therefore, was the donation of the right of way a betrayal of the rights of posterity, or a shrewd business move? If, by the construction of a railway through an undeveloped country, the corporation is the means of doubling land values, the increment accruing to the landowners being entirely providential, is society treating the corporation with equity and fairness when it says: "Thou canst take the chances of going broke, but if thy venture shall profit thee, thou shalt enjoy only the legal rate of interest"?

The writer believes in the existence of rational grounds for making the rate a function of the valuation in such utilities as gas companies, telephone companies, etc., but has the temerity, here and now, to express the opinion that the application of this theory to railway rates is utterly fatuous, and predicts that, in so far as materially altering present rate conditions is concerned, the Federal Valuation of Railways will prove to be "much ado about nothing."

It would be futile, however, even to attempt to stem the tide of public clamor for valuation. One who has had no experience in physical valuation can have no adequate conception of the obstacles encountered in such work. The writer's limited experience in this class of work has already taught him the necessity of depending on the actual engineering and accounting records, whenever they are available, rather than mere conjectures as to what the cost ought to be. For example, a certain passenger station would be appraised by probably nine out of ten experienced and expert engineers at about \$75 000, original cost. An examination of the original plans and accounting data, however, reveals extraordinary foundation difficulties, the conquest of which cost nearly \$20 000 more than the amount that would ordinarily be estimated. Again, a certain right of way was obtained through condemnation proceedings at a cost somewhat in excess of \$100 per

Mr. Green.

acre. This was the cost to the corporation, although the actual value of the land at that time was not more than $35 or $40 per acre. Would an appraisal which failed to take such matters into consideration do full justice to the corporation?

Again, it is argued that original cost should constitute present value for valuation purposes. Is it equitable to deny to corporations the increment which is freely conceded to others?

Referring to the proposal to deduct depreciation from cost of plant: As pointed out so ably by Mr. Humphreys, plant maintenance must be provided for out of earnings, and it would be contrary to reason to make it a charge against capital. On the other hand, the very purpose of depreciation reserves is to maintain unimpaired the capital originally invested—to keep the capital alive, as it were. As long as such reserves are provided, and original capital is not depleted, no deductions should be made from original cost of plant.

For valuation purposes, a railway should not be considered merely as a collection of various items, the value of which could be determined from an inventory. It should be treated as a living organism, so to speak. There is a vast difference, for example, between the summation of values of the constituent parts of a mule, when he is dead, as compared with his live value as a "going concern."

Mr. McCormick.

R. S. McCormick, M. Am. Soc. C. E. (by letter).—In undertaking the task of placing a valuation on railroad property, the Interstate Commerce Commission has been granted large powers, and the results of this valuation will be vital to the railway companies of the United States.

The figures furnished by the Commission will certainly be utilized for the purpose of fixing rates, or at least, in adjusting rates, and it is quite probable they will also be used in fixing the compensation to be paid in the purchase of railroad property outright by the Government.

The very able and complete manner in which Mr. Wilgus has presented this subject leaves little room for criticism by members of the Society familiar with railroad conditions. That the method of valuing by "Cost of Reproduction" is eminently fair can hardly be denied, and hence, seemingly, the only thing to discuss is the question of depreciation. Volumes have been written by a multitude of authors on this subject; the Courts have decided that "depreciation" must be considered in valuing public utilities, and, in view of the recent decision in the Minnesota Rate Case, the method of "Cost of Reproduction" with depreciation considered will probably be used in whole or in part in valuing the roads.

Just what depreciation is and how it should be applied in railroad valuation is a big question. Science teaches the indestructibility of matter, and we are all agreed that, once created, matter cannot be destroyed. We all know, however, that it can, and does, change very

materially. The component parts of a railroad company's property are made up of materials and things which are in continual process of change in form. They have a certain value in one form and perhaps another value in another form, until, as time goes on, they are of no value for their original purpose, and are dispensed with, or, as we say, renewed. Between the minute they were first used and the minute they will be discarded, some change in shape, form, appearance, or general utility has been going on, but, until actually discarded, their usefulness is not impaired as affecting other items; it only takes a lower standard. Mr. McCormick.

It is agreed by all that railroad property, by the very nature of its use, must be considered in a different light from ordinary private property. This is reasonable because of the large sums invested in such property, and because, speaking generally, it can only be used for one purpose, and for any other would be valueless, or, at least, of greatly lessened value; hence, it seems clear that its true value is made up of its value for this purpose and no other.

This value can be ascertained, in all cases, by the method so well outlined by Mr. Wilgus, namely, the Cost of Reproduction, provided intelligent men are guided by right principles so as to know when they have reproduced the property.

It is not true that making new every component part or unit of a railroad is reproducing that railroad. All will recognize this fact. Neither does the writer consider it fair treatment to such property that actual physical depreciation based on age be written off against each item or unit, when, as a whole, the item or unit, as classified, say, under the Interstate Commerce Commission Classification, is 100% efficient when joined with other items.

Therefore, a fair and equitable valuation must be based on the following principles:

(*a*). A standard should be fixed for the items under the Interstate Commerce Commission Classification, as far as these accounts cover measurable items, and all items included in these accounts should be given a marking, up to 100. This marking, however, is not to be based on the age of the item, but on its condition for the purpose for which it is utilized. The standard set as 100 should be a brief and explicit statement, applicable to each account, and in this way—from information as to condition, etc., taken in the field—the value of the item as a component part of the whole, rather than as a separate entity, can be determined. This arrangement should be followed for each mile of main track, for each 5- or 10-mile section, or otherwise, as seems most convenient. To show how this would work out: Account 4, "Grading," through Account 16, "Interlocking and Other Signal Apparatus", includes all accounts and all items covering a section of rail-

Mr. McCormick.

road track. For each of these accounts, the writer would define a standard and give that standard a rating of 100. "Grading", for instance, Account 4, would have a standard equal to a first-class, workman-like piece of construction, full width in all cuttings and embankments, well-shaped slopes, etc., etc., in fact, such a standard as any competent railroad construction engineer could easily define, keeping in mind the requirement mentioned under (*b*). All measurements of quantities are then made from the profile or in the field. If the work as performed meets the requirements of the standard, values are fixed at full prices to reproduce. Compacted embankments, seeded slopes, and other betterments of age, but on which no actual money was expended, will receive no advantage over newer work, except in the matter of adjusting quantities to cover same.

Now take Account 6, "Bridges, Trestles, and Culverts": A standard, covering the classification written as guided by (*b*), will be prepared. All structures will be measured, and their value estimated or fixed by data at hand. If the structure comes up to the standard, it is valued at renewal prices with no depreciation, though it may not be a new structure. The standard fixed for this classification must have sole reference to its condition and usefulness for the purpose, and not to its age. An honest engineer can grade such structures and ascertain their actual value by this method better than in any other way, and when the standard is once fixed, the proper value can be readily determined. Again, take Account 7, "Ties," or Account 8, "Rails": There will be ties in the track, and rails, also, which are not new. Could they be reproduced to answer their present purposes by any other means than by buying new ones? If not, then the standard should specify under this account that only new ties and new rails can be marked 100. Materials of this class should be valued at renewal prices and marked 100 if up to the standard in other respects.

Again, take Accounts 37 to 42, inclusive, "Equipment": Fixing a standard, based on condition, will obviate the large errors made in valuing such property by writing off depreciation based on life. Does any one doubt the efficiency and value as property, say, of a locomotive in good repair, which has not been worked beyond its capacity and is in every respect fitted to do its work? To a railroad company, is not such a machine fully as valuable as a new engine? In many cases it is more valuable. A standard, therefore, fitted to define what condition is entitled to 100, regardless of age alone, will give an equitable value, based on cost to reproduce this article as a component part of the whole. Every other account can be treated in the same way.

(*b*). In establishing the standard, locality or district should govern; that is to say, the same standard must not be applied to all sections of the country. The sections or zones should be first defined and a standard established for each.

Mr. McCormick.

(*c*). Land values should be standardized over each section or district, "Right of Way and Station Grounds," Account 2, and "Real Estate," Account 3, being separated. For real estate, values must be given as determined by adjoining property; for right of way and station grounds, a standard rating for railroad lands, based on values known to exist in that section of the country. The market value of adjoining lands may be used to assist in determining this standard rating.

By following these principles, a true valuation can be obtained. By this method the values placed on all roads will include additions and betterments which have been charged to earnings and are not represented by bonded indebtedness; hence, all physical property will be valued at its real worth, and if these additions and betterments have been made wisely, they will be represented by actual property value; if, on the other hand, they have been made extravagantly or wastefully, they will not be represented, and will not be accounted for. In the one case property is in evidence, in the other, investment; and we are all aware as to which can be protected legally.

As for values not represented by physical property, that is, promotion costs, interest charges, law expenses, etc., which go to swell the actual cost of a railroad property: these, of course, cannot be valued like physical property, but, under the proposed plan of referring all data to standards, they can be given consideration, as follows:

All items of this nature found charged up to Classifications 43 to 48, inclusive, should be totaled with Classification 1, "Engineering," where these records are available. After the full physical valuation is made for the entire system, compare the actual determined values with this total. After obtaining a full history of the system, leave it to a commission to fix a proper sum to add to this valuation to ascertain the true total valuation. Surely engineers know there is a definite relationship between the value of a work produced and the costs noted above to produce it. To create infers the utilization of the services of a creator. Certain legitimate charges for such services must, and no doubt will, be permitted in the total valuation. To reproduce new any one of the railway systems of the United States involves incorporating into the value of the inanimate objects composing the property, the cost of joining them together to make of the whole a living, running organism, and such costs are legitimately represented under "Engineering" and items under "General Expenditures" in the classification.

On American roads, during late years, large expenditures have been made which are of great benefit to the public, but earn nothing for the roads themselves. All such additions and improvements will tend to swell the total value for rate-making purposes.

After all, however, rates can hardly be based on values defined for each individual company—at least, not through rates. The only ad-

Mr. McCormick. justment, therefore, as stated by Mr. Lavis, is a blanket one for that section, and for that reason the writer considers his plan of a standard for each section the only practicable way of settling the question of depreciation and ascertaining how such a valuation can be utilized in rate adjustments or rate-making. Through rates will always be regulated by agreement between roads in the territory, under private ownership, as done at one time by competition. The powers of the commission can hardly go farther than to fix a maximum beyond which the roads cannot go. The road best equipped physically, due to low gradients, etc., and best managed will get the business or the lion's share, as at present. The rate covering a district or section can be regulated, and this rate should be based on a fair return on the true value of the property.

Mr. Corner. CHARLES CORNER, M. AM. SOC. C. E. (by letter).—The writer has read with much interest Mr. Wilgus' paper, together with the discussions thereon, and notes that his conclusion seems to be almost that of the pioneers in this important subject.

The matter was originated by the late Governor Hogg, of Texas, under whom the Texas Stock and Bond Law and Railroad Commission Act were passed, and administered by the first chairman, the Hon. J. H. Reagan, in the Nineties. It will be remembered that Senator Reagan was the Father of the Interstate Commerce Commission as well.

Subsequent work on this subject, throughout the United States, has arisen from the initiative of these men, and, as Engineer of the Railway Commission of Texas, from 1893 to 1898, the writer did a great deal of work on the valuation of the Texas Lines, which, up to that time, had not been contested by the companies interested. Communications by the writer on this subject were forwarded to *Engineering News*,* and are included in the "Bibliography on Valuation of Public Utilities."†

This "Bibliography" is of the utmost interest and value, but the writer does not think the Annual Reports of the Texas Railways are included in it. Certainly the reports for the dates referred to throw the greatest light on the beginnings of the movement, the credit of which belongs so largely to Governor Hogg and the late Judge Reagan. After the Texas policy was inaugurated, the latter was in direct communication with several other Southern States, which, thereafter, adopted similar policies and views.

The writer thinks that this is a matter which should be put on record, because, at the time, their action excited the greatest discussion and opposition. Their general views have been amply justified; the position which they took at that time was that of far-seeing statesmen.

* March 7th, 1895, and April 23d, 1896.

† *Transactions*, Am. Soc. C. E., Vol. LXXVI, p. 1280.

WILLIAM J. WILGUS, M. AM. SOC. C. E. (by letter).—The writer has a deep sense of obligation to those who have kindly participated in the discussion of his paper, as many of his own ideas have been clarified by the additional light that thereby has been cast on the subject. Mr. Crehore has generously credited him with an absence of desire "to complicate valuation work, and to seek out every possible pretext for making the assets, both tangible and intangible, look as big as possible"; and to this the writer feels that he may conscientiously reply that, in preparing this paper, he has had absolutely no other purpose in mind than an attempt to place his own views where they may be freely criticized by his fellow members and others, all in the interest of straight thinking. Mr. Wilgus.

Unlike Mr. Crehore, the writer does not believe that the *bona fide* stockholder as a class "gets something for nothing," nor that the stockholder is an "incumbrance." The fact that a small group of financiers may have abused the confidence and trust of innumerable innocent, if too confiding, investors of small means, seems in fairness to be no reason why experienced engineers should not attempt to formulate principles for guiding a valuation of property capitalized at some $20 000 000 000, for purposes that in the end may crystallize into a move for Government ownership.

Surely, Mr. Crehore would not ask that the subject shall be approached other than dispassionately in the hope that correct principles of valuation may be adduced, and that the facts as to any improper past return to the investor through interest and dividends and reinvested income, shall be then studied and a fair decision reached in the case of each road. Broad generalizations as to inordinate profits to investors in public utilities can hardly fail to do an injustice to a large proportion of the public that in good faith has invested amounts, great and small, in enterprises from which the entire public has reaped the enormous benefits referred to by Mr. Churchill and Mr. Green.

There are, no doubt, cases like those referred to by Mr. Hand where the public, through the rates, has paid an excessive return; but each instance requires detailed analysis to ascertain whether or not the annual distribution of cash in dividends and interest, plus the surplus reinvested in the property, really constitutes an inordinate reward to the investor. Many roads have been built up by putting back into the property moderate earnings that otherwise, with propriety, might have been distributed in cash to the stockholders, a praiseworthy proceeding that merits warm approval rather than condemnation.

In this connection it will be well to bear in mind that an approval of the theory that reinvested surplus and increases in land values are to be viewed as additional income to the stockholder, necessarily carries with it the proposition that such additional income is entitled to a return. This admitted, the accrued re-investments and other increases

Mr. Wilgus. in value constitute a sinking fund, made up of equal annual payments compounded at the rate of interest to which the service is entitled, for the full period of accumulation. For instance, an increase in 60 years of $100 000 000 in the value of a property, due to the increments mentioned, is equivalent to $187 572 annually, compounded at 6 per cent. This annual sum, added to the average annual dividends and interest actually disbursed in a given time, will produce the figure that should be taken as the total past annual return to the owners of the property in both cash and "kind". The point that the increment, if interpreted as income in an analysis of past results, is entitled to a return, has been missed by many. A similar error has been made by those who would count the increment as an additional return to the owner, and at the same time brand it as a depreciation reserve.

Several, notably Mr. Eaton, have expressed regret that the broader social problems of the day have not been touched on in the paper. The writer has felt that the subject of the valuation of railroads should be treated concretely, with a definite end in sight—the logical method of arriving at physical values—and that the manner in which the result should be used is a separate matter for independent discussion. The treatment of the so-called unearned increment, including donations from the community and reinvested surplus out of questionably excessive earnings of earlier years, is a question on which few as yet agree, and until the views of the majority are expressed through legislation that will affect all kinds of property alike, it does not seem equitable that one class of investment should now be selected for retro-active action. The correct course would appear to lie in making an appraisal that will stand the acid test of analysis, and then from a study of the past condition of each property make such disposition of the unearned increment as will be in consonance with a similar attitude toward other classes of property.

Mr. Gillette speaks of the supplanting of the competitive theory of railroad ownership with the agency theory, under which the public utility continues to be financed by the owner, but is indirectly managed by the Government through public regulation. The writer believes that this dual and contradictory relationship can be but temporary, the next logical step being nationalization. The enforcement, by the Interstate Commerce Commission and similar bodies, of expenditures for improvements on railroads will make obligatory the raising of new money by the owners through the sale of bonds or other form of prior obligations, and this in time will materially reduce or wipe out the stockholder's equity. If this final step to Government ownership is inevitable, it would seem better for the stockholder to encourage the transfer while he still has something to sell, that is, before his equity has been legally confiscated.

Mr. Wilgus.

There is a widespread feeling, evidenced by the remarks of Messrs. Eaton and Hand, that there should be but one measure of value. The laws of some States fix values for taxation purposes at "scrap-value," and the results of physical valuations on that basis, as in the instance of New Jersey, have been presented by technical journals to their readers, without cautioning them that the figures represent scrap and not reproductive values. The difference between the two may be made clear by citing the illustration of the office chair that is worth the full cost of reproduction as a part of a going concern, whereas, thrown on the market, at auction, it would bring a mere fraction of its cost.

The contributors to the discussion by no means agree on the principle that should be adopted in determining physical value. Messrs. Churchill, Gandolfo, Gillette, and Hand, see the practicability of ascertaining the original costs from the books or the amount of cash actually invested, while Messrs. Coombs, Harte, Humphreys, Ingersoll, Lavis, Molitor, Thomson, and Whinery join with the writer in considering this course to be generally impracticable. An intimate acquaintance with the records of many corporations, large and small, has demonstrated to the writer that the obtaining of correct, full, original-costs-to-date is so generally impossible that the use of that method would work wide injustice. No doubt there are some instances where book costs have been carefully kept so as accurately to reflect every item of expense chargeable to capital account, including organization, legal and administration expenses, interest during construction, and freight on construction materials, as well as all additions and betterments, with their proper burden of overhead charges; but the exceptions are so numerous that the use of a substitute method would be imperative, with the result that all roads would not be treated alike.

An objection that has been raised to the alternative for original-cost-to-date, namely cost-of-reproduction, is the inclusion therein of the increment of land values. Many contend that railroads, being public utilities, should not profit by the increment which is freely conceded to private individuals and corporations of another character. The justice of this contention is not apparent, as there are no laws in force for the guidance of investors in public utilities, which differentiate on this point between the two classes of ownership, nor is such contention upheld by the tax authorities, as forcefully pointed out by Mr. Aldrich. Arguments on this phase of the topic are well expressed by Mr. Green.

That any other than the reproductive theory will produce inconsistent results will be seen in the following case, which is illustrative of a situation that is very common.

Of three railroads running near each other through the same territory, Line A was built 30 years ago and has partial records of original-cost-to-date, Line B was constructed recently, and has com-

Mr. Wilgus. plete and accurate records of cost, and Line C, built 15 years ago, has no records of cost whatever. If the original-cost-to-date principle is adopted, the recently-built Line B, having full records, will be treated equitably; but Line A will suffer through incompleteness of data and loss of the increment of value that is contained in the estimate for Line B, and for Line C, possessing no records, the estimate cannot be determined by the adopted principle, and, therefore, must be arrived at by some other method which will be inconsistent with that used for the rival lines. On the other hand, if the reproductive principle is adopted, all roads will be treated exactly alike, and the older lines will not be placed at a disadvantage in comparison with the last built road.

Many endorse the reproductive method in theory, but in practice propose modifications that destroy the principle. The estimating of the cost of land at the same price as neighboring property, sometimes termed the basic or normal price, ignores the facts set forth by Messrs. Aldrich, Harte, Howard, and Whinery, that land for railroad purposes actually costs in excess of such price, and that the exclusion of a part or all of the overhead costs leaves out of the estimate elements which are as essential to the creation of a railroad as scaffolding in the building of structures. The omission of these items of cost is not in accord with either the original-cost-to-date theory or the reproduction method. Estimating in this manner has not the merit of following clearly any theory that will stand analysis, and is contrary to the experience of those who are familiar with the keeping of book costs or the actual building of railroads.

It has been said that reproductive estimates provide for "what it will cost to buy again land that will never be bought again, to duplicate property that will never have to be duplicated, and to build up a business that will never again have to be developed." Is not this the course that necessarily has to be followed in arriving at the value of any going concern, the earning power of which may not be used as the measure of its value? The appraiser of the physical value of a factory would base his estimates on a duplication of the plant, including the present-day reproductive value of its lands, structures, and cost of delevopment. What would be necessary in a simple instance of this kind is just as necessary in the case of a railroad.

Referring particularly to the matter of lands, and using the previously quoted illustration, Line A will be found to have paid for right of way 30 years ago, say, $600 per acre, and the modern Line B will have paid for land of precisely the same character, say, $1 500 per acre, or three times the basic value of neighboring property which in large blocks sells at an average of $500 per acre. The original-cost-to-date principle will give Line A $600 for exactly the same kind of property which, in the case of Line B, will be valued at

$1 500; and Line C, having no records, will have its land valued by some differing method. The basic method will give Line A $500 for that which cost it $600 30 years ago, Line B will be credited with $500 for that which cost it $1 500, and, again, will Line C require some alien treatment. The reproductive method would give all three roads the same price for the same character of land, would work no injustice by confiscation, and would give to the two older lines the same values that are embodied in the cost of the new rival. Mr. Wilgus.

In the Minnesota Rate Case, the United States Supreme Court ruled in favor of the basic-price method, but the comments of the Court on the testimony of the chief witness on land values give hope that a new presentation of the subject will lead to a future modification in this regard. As is well stated by Mr. Harte, the railroads in the case mentioned failed to bring out "the fact that 'the fair average market value of similar land in the vicinity' is the value of land in right-of-way shape, and not that of land in normal parcels."

Many instances may be cited where railroads in recent years, under Court decrees in condemnation cases as well as by private purchase, have paid several times the amounts that would result from the use of the basic or neighboring-value method; and it is evident that the use of the method prescribed in the Minnesota Rate Case would work confiscation to many roads and entirely discourage the creation of new ones.

Mr. Crehore's proposal that all owners of property shall fix the value of their holdings as a basis for taxation and sale has its attractive side, but the benefits which he anticipates in the acquiring of lands for public utilities at minimum prices, would hardly materialize, in view of the question of severance and other damages that would still remain for settlement. That the property owner voluntarily should place a higher valuation on the part of his holdings through which he might imagine a railroad would be likely to pass, is crediting him with a degree of prophetic vision and engineering skill that is unpossessed by the average man; and the payment of excess taxes on such a product of his imagination would be to him a costly venture from which the chance of repayment would be, to say the least, exceedingly remote.

The question of how to handle depreciation has developed two widely divergent views. Messrs. Eaton, Gillette, Humphreys, Ingersoll, Lavis, Molitor, Taylor, and Waitt, and, to a limited degree, Messrs. Green, Harte, and Whinery, believe with the writer that no deduction therefor should be made from the cost of reproduction new, and Messrs. Brinkley, Coombs, Crehore, Gandolfo, Nicolaysen, and Willoughby think otherwise.

It is possible that this difference of opinion is to a large extent due to a failure by each side to grasp the reasons that are guiding

Mr. Wilgus. the other; and a somewhat extended dissertation on the subject may be pardonable, illuminated as it is by the ideas brought out in the discussion.

Depreciation of railroad property, as generally understood, consists of physical retrogression, due to usage and decay, and to lessened effectiveness through obsolescence and inadequacy.

This physical retrogression calls for two classes of expenditures, namely: (1) current maintenance applied to those items which need constant attention in the ordinary upkeep of road and equipment; and (2) deferred maintenance of features that cannot be economically restored, renewed, or replaced until they reach maturity.

Sound practice, enforced by the rules of National and State regulatory commissions, requires that expenditures for both current and deferred maintenance of public utilities shall be charged to operating expenses, and not to capital. Stated differently, depreciation is declared to be an item of expense to be defrayed from the rate, and not wastage of capital to be paid for through the issue of securities.

A well-run corporation will maintain its property so that current repairs and renewals will not be allowed to fall behind, and it will also regulate its distribution of dividends to stockholders so that the combined depreciation reserves and profit and loss surplus will be not less than the accruals of deferred maintenance. In this connection it should be added that the profit and loss surplus of a railroad company is just as much a reserve fund for offsetting depreciation as if so labeled.

A failure thus to provide for these two classes of depreciation is usually the result of over-payment of dividends, and eventually brings its own punishment through the necessity of a reduction or suspension of dividends during the period of rehabilitation. This course is obligatory, as charges for rehabilitation legally can only be made through income.

It will thus be seen that stockholders who unwisely or improperly overpay themselves in dividends, are simply creating a liability that must be repaid through a lessened later return on their investment. They are not, as Mr. Crehore states, in the position of "eating their cake and having it too," for the reason that they must restore the "cake" from their own resources; they are prohibited from doing so through capital account.

If this line of reasoning is correct, the investor is entitled to a rate sufficiently large to: (*a*), defray operating expenses, including current maintenance and taxes; (*b*), provide an allowance for deferred maintenance; and (*c*), yield a fair return on the investment unimpaired by depreciation; with the understanding, however, that if the allowance for deferred maintenance is not properly conserved, its

restoration shall be effected from the investors' return which otherwise would be available for dividends. In other words, (*a*) and (*b*) are preferred obligations. Mr. Wilgus.

All this brings us back to the proposition that, under the law, physical depreciation of both classes, current and deferred, is a stockholder's liability and not a wastage of capital, and, consequently, it should not be deducted from the investment in determining a question of rates.

The railroad is a very complex organism, and the question of depreciation is correspondingly involved. A more simple illustration may assist in clarifying the subject.

The owner of a ferry-boat is admittedly entitled to a rate that will produce earnings sufficient to pay operating expenses, including all repairs, renewals, and taxes, and, say, 6% on the investment. By gouging out and restoring each spot of rot or wear as it appears, and replacing each nail or bolt the moment that it commences to chafe or rust, the boat may be maintained practically new for an indefinite period; and in that event no question would be raised as to the owner's title to the full 6% return on the unimpaired investment, as there would be no depreciation. But this method of repairing, being very costly and, therefore, adverse to public interest, it is considered better practice to confine current repairs and minor renewals to those parts which may be repaired economically from day to day, and pay at regular intervals into a deferred maintenance sinking fund an amount which, with accumulations at compound interest, will produce a sum at the end of a given period with which to restore the old boat or purchase a new one. Can it be fairly said that in the latter case the return on the investment must constantly fall from 6% on the full amount when the boat is new, to zero at the date of restoration or replacement; whereas, in the former case, so much less to the public interest, the full rate should continue without abatement? If so, it would seem far better for the investor to abstain from the common carrier field, and loan his funds in a manner that will guarantee the same rate of return without confiscation of principal.

It is admitted by many that the arguments for the non-deduction of depreciation are well taken in cases where an ample reserve has been accumulated in outside investments, as in the ferry-boat example, and in cases where the property has not been enriched through improvements paid for from income; but the claim is made that in instances of physical valuation where no such outside reserve or other assets exist, and funds for off-setting depreciation have been reinvested in the improvement of the property in the shape of additions and betterments, there is a clear inequity in permitting a return to the owner on the portion of the property so reinvested. The

Mr. Wilgus.

answers are: First, that the impracticability of drawing lines sharply between improvements paid for through capital and others paid for from income, makes imperative the adoption of some rule that will apply uniformly to all; second, that the methods of accounting established by the Interstate Commerce Commission prohibit the practice which would become necessary of charging repairs and renewals to capital, if items originally appraised in their depreciated condition later were raised to their restored value; third, that the treatment of past additions and betterments as the equivalent of additional income to the owner removes those items from the category of depreciation reserves; and fourth, that on the owner rests the continuing duty of replacing depreciation out of the allowed rate, making good from his own share thereof any deficiencies due to over-payment of dividends or other diversions of the part of the rate intended for current and deferred maintenance.

Many are the instances which may be quoted of a reduction or suspension of dividends from the latter cause. Railroads thus situated could not increase their rates as a means of rehabilitating their properties, and have been forced to forego a full or even partial return on the investment until the necessary repairs and renewals had been effected out of what otherwise would have been distributable to the stockholders. Certainly, neither sound financing nor the accounting rules of the Interstate Commerce Commission, would sanction the capitalizing of expenditures for rehabilitation; nor would the laws of competition or the rules of regulatory commissions permit a raise of rates to accomplish the same purpose.

Not only from the standpoint of logic does it appear that in questions of rate regulation, depreciation should not be deducted from the principal, but also, as a practical matter, this course seems to be the only one to adopt. Current maintenance fluctuates during the year so that what may be a fair estimate in one month is unfair in another month. For instance, in the fall the depreciation on ties in the railroads of the United States amounts to some \$60 000 000 less than a few months earlier in the year prior to the commencement of annual renewals. Costly structures, if estimated at a depreciated value, later will be found to have been rebuilt or replaced, with a corresponding large increase in value. To add these growths in value, through restoration of depreciation, to a previously determined capital sum, in effect would amount to a capitalization of items which, under the law, had been charged to expenses—a course that speaks for unsettled rates as well as a violation of accounting principles established by the Interstate Commerce Commission. Then, too, the annual revision of depreciation, unlike additions and betterments, cannot be recorded through book entries, but necessarily must be effected through a recurrent field inspection of the multitude of items

that enter into the construction of railroads,—a truly monumental task. There is the further point raised by Mr. Molitor, that what is deemed to be a depreciated condition for high-class traffic may be as good as new for a less exacting service. Moreover, the adoption of depreciated values, with their shortened lives, would call for the inclusion in the rate of higher percentages of depreciation than would be necessary were the same objects estimated at their cost new, and this would practically nullify the saving to the public of using depreciated values as a basis for fixing the investor's return. Mr. Wilgus.

The recent disastrous flood damage in the Middle West is a good illustration of the matter at issue. Railroad property was depreciated to the extent of many millions of dollars, all of which had to be restored out of earnings and profit and loss surplus, without an increase of capital on which rate-payers would be expected to defray the interest. Surely, it would not be equitable to impose a further burden on the stockholders by a lessened return on the depreciated investment at the very time when they are compelled to forego a part of their savings or profit in meeting their liability to restore their property to full working condition. To do so would amount to a double burden on the stockholders through a wastage of capital and reduction of earnings or surplus.

Several of the contributors to the discussion consider that no deduction should be made for the class of depreciation that is repaired through current maintenance, but that deduction should be made in cases of deferred maintenance, as in the instance of the coal pocket cited by the writer, where no sinking fund has been provided. For the reasons above given, the replacement of a structure like the coal pocket is a liability of the company, to be paid for out of earnings otherwise applicable to dividends or out of profit and loss surplus; and the avoidance of the bookkeeping detail of separately labeling a fund for each structure should not affect the principles underlying the subject.

May it not be said, therefore, that in questions affecting rates, the desirability of avoiding constant fluctuations of rates, compliance with the accounting rules established by public regulatory commissions, the avoidance of confusion and needless complications, and sound logic, all point to the correctness of the claim that the value of railroad property should be considered unimpaired by depreciation; and that on the stockholder rests the obligation of restoring depreciation, either from profit and loss surplus or "reserves", or through a lessening of the return on his investment during the period of rehabilitation.

It is true that the United States Supreme Court, in the recently decided Minnesota Rate Case, did not take this view, but may we not conclude that this was the result of an inadequate presentation

Mr. Wilgus. of the principles underlying this important question, rather than a final endorsement by the Court of the general proposition that, in matters affecting return on capital, depreciation should be deducted from the investment.

The claim has been made that if the appreciated value of right of way and real estate is allowed, a deduction for physical depreciation is entirely proper. This does not seem to be a logical contention, for the reason that the appreciation of land values, being an additional return to the investor, plainly should be credited to capital account; while depreciation is of a physical nature caused by temporary retrogression, and is a charge to expenses and not to capital account.

On the very important item of overhead charges there appears to be little difference of opinion among those discussing the paper.

Beyond question, as brought out by Mr. Gillette, the percentage for contingencies should be comparatively small if reliable data as to quantities and up-to-date costs are obtainable from the records; but where estimates are necessarily made without the benefit of such precise knowledge, and the adopted unit prices are not inflated, a sufficiently liberal allowance for contingencies should be made, precisely as would be done by the experienced engineer in preparing preliminary estimates for any project. It has always seemed to the writer that the item of contingencies should be provided for through a percentage that will be open to inspection and discussion, rather than through an arbitrary increase of unit prices where it would be more or less concealed.

Mr. Gandolfo considers that no provision should be made for the educational stage during which construction gradually draws to a close, and traffic is built up from nothing to the full volume on which the income that may be in question is earned. With an object so simple as an automobile, the dealer devotes his time gratis to educate a customer and to the repair and replacement of any defective or imperfect parts, before the transaction is closed; and the cost of labor and materials for thus breaking in the car and educating the user is contained in the price. So, too, with a railroad, must certain expenses be provided for in the estimated cost of reproduction, for breaking in the plant, and educating the forces which are to supervise the moving of the existing volume of traffic. A railroad's operating organism does not spring, Minerva-like, into being, fully equipped and trained for a complicated service; it must pass gradually from the period of active construction to the culmination in growth of the going concern; and, as Mr. Lavis points out, it is by a suitable allowance for interest charges that this going value may be measured.

In the organization of the valuation corps largely rests the success or failure of the outcome of a physical valuation. Beyond question, the qualities mentioned by Mr. Gillette are desirable, and, in most instances, essential; but the one feature which he omits, experience, would seem to be the prime need, if the results are to stand. This is particularly mentioned by Mr. Waitt and Mr. Norcross. The chiefs of field parties certainly should have the very qualities that Mr. Brinkley would not credit to them, capacity and experience for observing and recording the condition of the property. Mr. Wilgus.

As stated by Mr. Molitor, a low-grade line through a populous country has a distinct advantage over a competitive high-grade line through a sparsely settled region; but with net earnings, in which the rate at issue is a factor, eliminated as a measure of such advantage, the selection of some other yardstick of intangible values is a problem on which no light has yet been shed. The writer has purposely abstained from suggesting a measure for such intangible values as traffic productivity and operating effectiveness, because he has been unable as yet to define in his own mind just how they may be estimated, other than for comparative purposes under known local conditions.

Paper No. 1288

DERIVATION OF RUN-OFF FROM RAINFALL DATA.

By Joel D. Justin, Assoc. M. Am. Soc. C. E.

With Discussion by Messrs. L. J. Le Conte, R. B. H. Begg, R. G. Clifford, Robert E. Horton, J. William Link, J. K. Finch, and Joel D. Justin.

In the study of a drainage basin which is to be utilized for water supply or water power, it frequently happens that there is a dearth or utter lack of run-off data, though more or less precipitation data are almost always available.

It was with the desire of finding out if it were not possible to develop some rational method of deriving run-off from rainfall data on various water-sheds, that the present study was undertaken.

The quantity of rainfall appearing as run-off on any water-shed is governed by many conditions, chief among which are character of vegetation, extent of forest covering, prevailing winds, relative humidity of atmosphere, barometric pressure, percentage of water surface, geology of basin, slope, and mean annual temperature.

Before investigating the manner in which the relations between rainfall and run-off differ on various water-sheds, the writer will examine into the manner in which they vary from year to year on any one water-shed.

The late George W. Rafter, M. Am. Soc. C. E., showed in his paper, "The Relation of Rainfall to Run-off,"* that the relation of rainfall

* Geological Survey, Water Supply Paper No. 80.

to run-off on a water-shed could often be expressed as an exponential equation. For the Upper Hudson he gives the two equations, $P^2 = 84.5\ R$ and $P^{1.77} = 34.3\ R$; P being the annual precipitation and R the annual run-off, in inches, on the water-shed. He does not, however, suggest any constant value for the exponent of P or R for other water-sheds.

After plotting many rainfall and run-off data, the writer became convinced that the relations between rainfall and run-off on almost every water-shed could be expressed by a logarithmic equation, of the form, $C = K\ R^n$, in which C = annual run-off, R = annual rainfall, K is an abstract number, constant for any one water-shed, and n is an exponent constant for the water-shed.

In solving the equations it was found that n always came out nearly equal to 2; hence it was chosen as a constant for all water-sheds and always equal to 2.

The writer then plotted, on logarithmic cross-section paper, using annual run-off in inches as ordinates and annual rainfall in inches as abscissas, a considerable portion of the available reliable data. He found that on all these water-sheds the relation may be well expressed by the formula:

$$C = KR^2,$$

in which C is the annual run-off, in inches; R is the annual rainfall, in inches; and K is a constant which is different for each water-shed, and has a value depending on those conditions which make the relations between rainfall and run-off on one water-shed different from those on another.

Most hydrologists in America choose December 1st as the beginning and ending of the water year; others use October 1st, and in England September 1st is the date selected, the object, of course, being to choose a time when the ground-water conditions will be more likely to be the same from year to year.

In the accompanying diagrams, both October 1st and December 1st, have been used, the date for beginning and closing the water year being stated in each case.

Accuracy of Data.—The accuracy of existing data does not justify precision. On some of the territories for which diagrams are presented (Figs. 1 to 19) there is one rainfall station per 1 000 sq. miles of water-shed. In the computation of run-off, a discrepancy of 1 or

2 in. is not worthy of discussion. In most cases one can safely assume a probable error of 10% in the observed rainfall for any one year for most water-sheds. The error in any individual record at a certain station is undoubtedly less than this in most cases, but when several rainfall stations are combined to give the rainfall for an entire water-shed, the probable error is increased. In general, the larger the number of rainfall stations on a water-shed the less the probable error.

Run-off records are usually more accurate; but, up to a few years ago, few streams were accurately gauged, and the error was generally positive. At present many of the records of the Water Resources Branch of the United States Geological Survey and of many municipal water supplies, are all that could be desired; the probable error not exceeding 5 per cent. Perhaps one of the most accurate records, for purposes of comparison between rainfall and run-off, is that on the Esopus water-shed (area 239 sq. miles) of the Catskill water supply system of New York City. On this water-shed there have been maintained from 8 to 13 well-distributed rainfall stations. The measurement of run-off has been made at a concrete weir, especially built for the purpose, with a cross-section corresponding to one of the models used in extensive experiments at the Cornell University Hydraulic Laboratory, described in Water Supply Paper No. 200, of the U. S. Geological Survey.

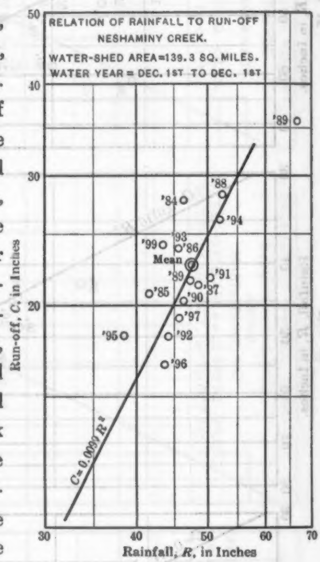

FIG. 19.

The relation between rainfall and run-off on this water-shed is shown in Fig. 1. It will be noted that all the points fall almost precisely on the curve, $C = 0.01292R^2$.

When rainfall and run-off data are plotted on diagrams, such as those presented, the probable error in using the resulting curves in mass-curve storage studies is much reduced.

Effect of Proportion of Water Surface.—The writer believes that many hydrologists have exaggerated the importance of the effect of water surfaces on a water-shed in decreasing the quantity of run-off. Aside from regulating the distribution of the run-off throughout the year, the effect of any ordinary proportion of water surface is so small as to be negligible.

This is well shown by Mr. Rafter.* In discussing the percentage of water surface on the Croton water-shed (3.56%) he says:

"It may at first thought be imagined that these large water surfaces exposed to evaporation have considerably increased the ground evaporation over the entire catchment. When, however, one considers that it is only the difference between what a water-surface evaporation and what a ground-surface evaporation would be, the difference is seen to be not very much. For instance, assuming the water-surface evaporation at 36 inches per year and the ground-surface evaporation at 27 inches per year, the difference becomes 9 inches. With 12 square miles of water surface in 1900, giving 3.56 per cent. of the whole, the excess of water-surface evaporation over ground-surface evaporation is 0.32 of an inch, a quantity which is so far within the limit of possible error in other directions as to be negligible."

Grouping of Data by Water Years.—In the comparison of rainfall and run-off grouped by water years, beginning October 1st, December 1st, or some other date, it is frequently observed that, on any water-shed, certain years, having the same recorded rainfall, have recorded run-off differing by from 1 to 4 in.

In the diagrams, although most of the points fall on or near the curves represented by the equation, $C = K R^2$, there are some which are at some distance from the curves. Noting this condition, many claim it as proof that there is no definite relation between rainfall and run-off. In reality, the apparent discrepancy is due merely to variation from year to year in ground-water conditions on the date arbitrarily assumed for beginning the water year. The fact that a point does not fall on the curve does not necessarily show that the observations are at fault, but in most cases it does indicate that the date of beginning the water year assumed for the water-shed is not the true one for that particular year.

It is an error to consider the water year as a hard and fast division of time. Many of the points, which in the diagrams plot some distance from that curve, would fall directly on or very near it, had

* "The Relation of Rainfall to Run-off."

the first of the preceding or succeeding month been used for beginning the water year.

The true water year does not begin or end at any particular date, but should be regulated so that ground-water conditions are nearly constant on the dates selected for the beginning of such years. It is believed that, if this could be done, all points for which the data are accurate would fall on or near the curve represented by the equation, $C = K R^2$.

Owing, however, to the almost utter lack of data on ground-water levels, it is impracticable to adopt this method of division. Especially in the study of large storage propositions, the apparent discrepancies will balance each other, and will not affect the conclusions.

Manner in Which the Relations Between Rainfall and Run-off Vary from One Water-shed to Another.—It has frequently been observed that, other things being equal, a steep water-shed will have a greater run-off for the same rainfall than a flat one. The water, staying on the water-shed a shorter length of time, has less chance to evaporate. Mr. Vermeule has shown successfully the great influence which the mean annual temperature of a water-shed has on the relation of rainfall to run-off.

These two elements, slope and mean annual temperature, the writer believes, are, in general, the chief factors determining the manner in which the relation between rainfall and run-off vary from one water-shed to another. Hence he will use them in determining the value of K.

The slope of a water-shed may be defined as the difference in elevation between the highest and lowest points divided by the square root of the area.

The proper value for the mean annual temperature of a water-shed can generally be determined by a study of the data published by the United States Weather Bureau in the "Summary of Climatological Data for the United States, by Sections." In using these data, it sometimes happens, especially on mountainous water-sheds, that all the observations are at stations in the valleys. On such a water-shed the mean annual temperature frequently varies directly with the elevation. In such a case, a practical method of determining the mean annual temperature would be as follows:

(1) Take the average temperature at the stations;
(2) The average elevation for the same stations;

(3) The average elevation of the water-shed = the elevation of the highest point plus the elevation of the lowest, divided by 2;

(4) Take the difference between the average elevation of the stations and the average elevation of the water-shed;

(5) Multiply this by the mean difference in temperature per foot of increase in elevation;

(6) Finally, subtracting this from the average temperature at the stations will give the mean annual temperature of the water-shed.

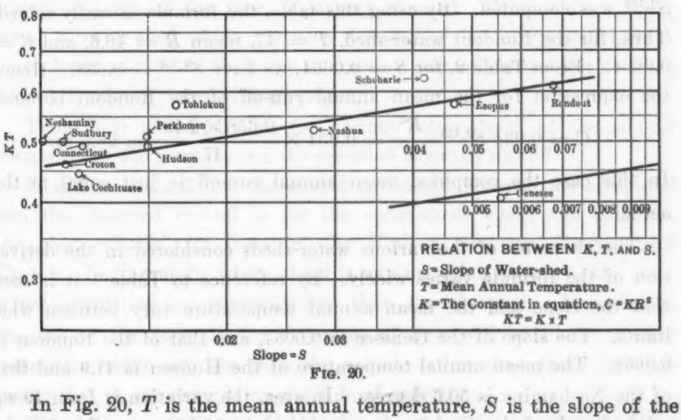

FIG. 20.

In Fig. 20, T is the mean annual temperature, S is the slope of the water-shed, determined as previously described, and K is the constant in the equation, $C = K R^2$.

It was found that for several water-sheds having about the same value of S, K varied very nearly as the first power of T. In Fig. 20 the values of KT (the product of K and T) have been plotted as ordinates and the values of S as abscissas.

Table 1 gives the values of K, T, S, and KT, for various water-sheds.

Picking values off the logarithmic curve in Fig. 20, and solving the equation,

$$K\,T = P\,S^x,$$

P being the unknown coefficient and x the unknown exponent, we have, for the equation of the curve, $K\,T = 0.934\,S^{0.155}$

$$\text{but } C = K\,R^2,$$

$$\text{whence } C = 0.934\,S^{0.155}\,\frac{R^2}{T},$$

which is the general formula for the relation of run-off to rainfall.

C = Annual run-off, in inches, on the water-shed;

R = Annual rainfall, in inches, on the water-shed;

S = Slope of the water-shed, equals the elevation of the highest point minus the elevation of the lowest point divided by the square root of the area;

T = Mean annual temperature of the water-shed, in degrees, Fahrenheit.

For convenience in using the formula, Table 2, giving values of $S^{0.155}$ was computed. By using this table, the formula is easily solved. Thus, for the Rondout water-shed, $T = 47$, mean $R = 46.6$, and $S = 0.0664$. From Table 2, for $S = 0.0664$, we have $S^{0.155} = 0.658$. Hence the expression for the mean annual run-off of the Rondout becomes

$$C = 0.934\,S^{0.155}\,\frac{R^2}{T} = 0.934 \times \frac{0.658 \times 2\,180}{47} = 28.5 \text{ in.}$$

In this case the computed mean annual run-off is just equal to the actual.

The character of the various water-sheds considered in the derivation of the formula varies widely. By reference to Table 1 it is seen that the slope and the mean annual temperature vary between wide limits. The slope of the Genesee is 0.0054, and that of the Rondout is 0.0664. The mean annual temperature of the Hudson is 41.9 and that of the Neshaminy is 50.6 degrees. In area, the variation is from 19 sq. miles for the Lake Cochituate water-shed to 10 234 sq. miles for the Connecticut at Hartford. In the matter of forestation, the variation

is also large, from the water-shed of the Genesee, with its gently rolling farm lands and few woods, to the heavily forested head-waters of the Rondout and Upper Hudson. The effect of forests on the quantity of rainfall and run-off is believed to be slight, but, on the distribution of run-off throughout the year, it is very marked. Other things being equal, a water-shed which has been denuded of its forests will have a much lower minimum discharge in summer and will be subject to more violent floods in times of high water.

Table 3 is a comparison, for various water-sheds, of the run-off computed by the formula and the recorded observed run-off.

It will be noticed that the closest agreement between the computed and the observed run-off is for the water-sheds where the data are the most reliable, for instance, the Hudson, Genesee, Esopus, and Croton. Furthermore, where there is any material variation, the computed quantities are generally less than the observed. Accordingly, the use of the formula for estimates of flow will be likely to give quantities which are less than the actual, rather than those that are more; that is, the error is on the side of safety.

The formula is also applicable for the computation of run-off for individual years. For illustration, take two water-sheds, the Hudson

and the Esopus. In the case of the Hudson, $S = 0.0149$ and $T = 41.9$, and the formula becomes, $C = 0.934 \dfrac{0.520\,R^2}{41.9}$,

$$\text{or } C = 0.0116\,R^2.$$

In the case of the Esopus, $S = 0.0468$ and $T = 44.5$, and the formula becomes $C = 0.934 \dfrac{0.623\,R^2}{44.5} = 0.0130\,R^2$.

1911.........	37.0	19.3	17.8	1.5

These two illustrations serve to show the degree of accuracy that may be expected in the use of the formula when the rainfall and temperature data are fairly accurate.

The Supplying of Missing Records.—It sometimes happens that only 2 or 3 years of good run-off records have been kept on a watershed, and that rainfall records are available for a number of years. In such a case, the record may be extended in the following manner.

Plot on logarithmic cross-section paper points for the 2 or 3 years of known run-off, using rainfall as abscissas and run-off as ordinates. Compute the run-off for several other years, using the formula, $C = 0.934\ S^{0.155}\ \frac{R^2}{T}$. Plot the corresponding points. Then draw a straight line parallel to the line, $Y = X^2$, among these points, giving greater weight to the observed data. This line will be represented by the equation, $C = K\ R^2$. Having this curve, the run-off for any year may be read off, using the rainfall as argument.

Application to the Mass-Curve.—Engineers are frequently called on to construct reservoirs of considerable capacity on water-sheds where accurate run-off data are lacking. For the determination of the necessary capacity of a proposed reservoir, the mass-curve is the accepted method. Having given a water-shed without run-off data, but with rainfall records available, a satisfactory mass-curve may be constructed by using the formula, $C = 0.934\ S^{0.155}\ \frac{R^2}{T}$. The values of S and T are generally easy of determination for any particular water-shed.

In using this formula for the construction of a mass-curve, it is applied to the rainfall for each month consecutively, and the resulting monthly run-off is used in constructing the mass-curve in the usual manner. Of course, using the formula in this way, the resulting com-

puted run-off for individual months will often be very different from the actual; but, in the study of large water-power or water-supply projects, where water must be stored for several months, this will not affect the conclusions as to the necessary size of the reservoir for a given draft.

The most expeditious method of applying the formula for this purpose is as follows:

Compute several values of C for given monthly values of R. Plot these computed values of C, with the corresponding values of R, on logarithmic cross-section paper. The points will lie in a straight line. This logarithmic curve may then be used for picking off values of C for given values of R.

On Plate V are shown two mass-curves for the Croton water shed. The upper curve was obtained from the recorded run-off data, and the points on the lower curve were computed by the formula, $C = 0.934\ S^{0.155} \frac{R^2}{T}$. It will be noticed that the cumulative totals of the observed run-off for 37 years differ from the computed by about 3%, the computed being less than the observed. A draft on the water-shed of 1.65 in. per month, or 320 000 000 gal. per day, was assumed and applied to the curves. The greatest depletion shown on the curve of observed run-off was 14.2 in., and the mass-curve of computed run-off showed a depletion of 18 in., a difference of 21 per cent. This difference, however, is on the safe side. It is customary to build reservoirs with a capacity of from 20 to 30% in excess of the depletion shown by the mass-curve. Had there been no run-off data in existence on the Croton water-shed, a reservoir of sufficient capacity could have been decided on from a study of the computed mass-curve.

In a similar manner, two mass-curves were plotted for the Nashua water-shed, one from the observed run-off data and the other from computed run-off data obtained by using the formula. A draft of 1.852 in. per month, or 125 000 000 gal. per day, was assumed. The greatest depletion on the curve of observed run-off was 10 in., and on the curve of computed run-off, 12 in., an error which is again on the safe side.

The mass-curves of observed run-off and of computed run-off were plotted for the Esopus water-shed. A draft of 1.825 in., or 250 000 000 gal. per day, was assumed. For the curve of observed run-off, the

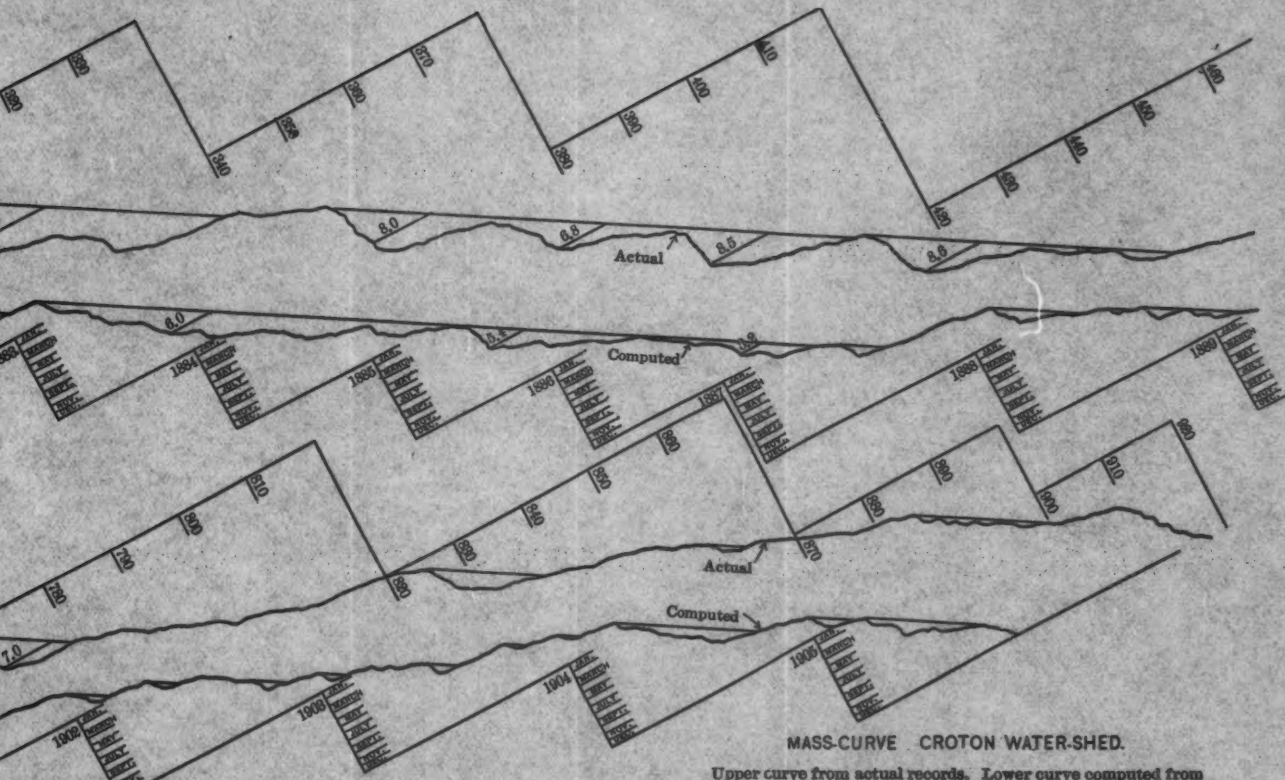
PLATE V.
TRANS. AM. SOC. CIV. ENGRS.
VOL. LXXVII, No. 1288.
JUSTIN ON
DERIVATION OF RUN-OFF FROM RAINFALL DATA.



MASS-CURVE CROTON WATER-SHED.

Upper curve from actual records. Lower curve computed from rainfall, using the formula, $C=0.934\,S^{0.155}\frac{R^2}{T}$, in which C=run-off S=slope, T=mean annual temperature, R=rainfall.
S for Croton=0.0110. T for Croton=49

greatest depletion was 8.2 in., and, for the curve of computed run-off, the greatest depletion was 7.5 in. The difference, 0.7 in., though not on the safe side, is so small that it could not affect materially the size of the reservoir decided on.

Conclusions.—The writer is not of the opinion that the gauging of streams and the accumulation of run-off data should be abandoned, and the method herein described established in their place. Accurate run-off data are scarce, and engineers need far more. These methods and formulas are applicable to water-sheds where run-off data are meager or lacking, and it is believed that they will give more reliable results than those now generally in use.

The formula, $C = 0.934\, S^{0.155} \frac{R^2}{T}$, is, the writer believes, applicable to the Eastern United States, and, in general, should give results within 10% of the true run-off. In applying the formula to other water-sheds, the writer would advise caution. Although the formula is believed to be general, it is possible that, if more data were at hand on the relation of run-off to rainfall, the value of the constant (here 0.934) and of the exponent of S (0.155) might vary somewhat in other sections of the country, where there is a marked difference in climatic conditions.

Of course, if this formula is applied to the rainfall for some particular month it will not give the true run-off. It has been shown, however, that it may be used for obtaining monthly run-off, and that the mass-curve when plotted gives depletions which do not differ materially from those obtained when the observed monthly run-off is used in constructing it.

At first sight, the application of the formula may appear to be complicated, but, by using Table 2, which gives the values of $S^{0.155}$, it is simple; and if logarithmic plotting is utilized, as suggested, it becomes merely a matter of reading off the curve.

DISCUSSION

Mr. Le Conte. L. J. Le Conte, M. Am. Soc. C. E. (by letter).—The formula presented by the author is very ingenious and seems to fit the cases considered with surprising closeness. Where the basin is for water supply and power purposes, however, the writer would particularly caution the young engineer against making any practical use of the long average run-off, which is that furnished by the formula.

The water supply storage reservoirs at and near San Francisco, Cal., have been in constant use for 43 years, hence the practical results obtained are very interesting. The long average rainfall is 40 in., and the long average run-off is 8 in., or 20 per cent. The important fact remains, however, that at intervals of 10 or 12 years there are 3 years in succession in which the rainfall is only 18 or 20 in., and is distributed so uniformly that the thirsty ground takes it all, and, as a result, there is absolutely no run-off for 600 days or more. The reservoirs, therefore, have to be large enough to hold a 3 years' supply without any possible hope of replenishment.

The same important feature is noticed on the Sudbury water-shed,* where the record for 37 years shows a long average yield of 1 000 000 gal. per day per sq. mile of water-shed; but, during the three successive years, 1909, 1910, and 1911, the average yield was only 550 000 gal. per day per sq. mile. This is practically the limit of usefulness for this water-shed. The record shows that in 1888 the average yield was 1 700 000 gal. per day per sq. mile of water-shed, but as this only happens once in about 25 years, this isolated fact has no practical value for water-supply purposes.

Mr. Begg. R. B. H. Begg, Assoc. M. Am. Soc. C. E. (by letter).—Mr. Justin's paper is an interesting addition to an important subject, but the writer would like to call attention to the danger of attempting to apply any general formula to so complicated a matter as the relation of rainfall to run-off. The writer also wishes to present a hitherto unpublished run-off curve (Fig. 21), which may be of interest. This curve shows the relation of run-off to rainfall for the principal water-sheds of Kansas. The run-off figures were taken from the stream guagings of the U. S. Geological Survey, and the rainfall from the reports of the U. S. Weather Bureau. The points plotted, with very few exceptions, fell very close to the final curve. The principal point of interest in this curve is the great difference between it and the curves for the Northeastern States, which are the ones usually seen.

The conditions governing the run-off in Kansas are quite different from those in the East; of these the two most important are the

* Twelfth Annual Report, Metropolitan Water and Sewerage Board of Massachusetts, 1912, p. 58.

slight slope of the drainage areas and the fact that the greatest rainfall occurs in summer, when vegetation is most abundant, and, consequently, evaporation from the ground is greatest. It will be noticed that, for a rainfall of 40 in. on the water-sheds mentioned by Mr. Mr. Begg.

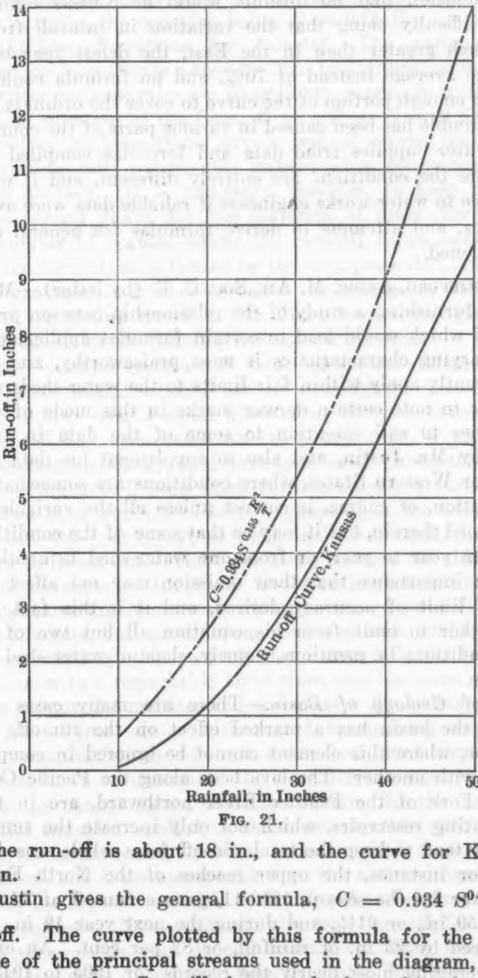


FIG. 21.

Justin, the run-off is about 18 in., and the curve for Kansas gives only 6.1 in.

Mr. Justin gives the general formula, $C = 0.934\ S^{0.155}\ \frac{R^2}{T}$, for the run-off. The curve plotted by this formula for the Republican River, one of the principal streams used in the diagram, Fig. 21, is on the same scale. It will be noted that this formula gives

Mr. Begg. results about 40% greater than those obtained from the curve plotted from actual measurements for rainfalls of 30 in. or more, and for smaller rainfalls it gives even greater discrepancies. The writer attempted unsuccessfully to derive a formula that would fit this curve, and came to the conclusion that no formula would fit Kansas conditions, the principal difficulty being that the variation in rainfall from year to year is much greater than in the East, the driest year being about 50% of the average instead of 70%, and no formula could be found to fit a long enough portion of the curve to cover the ordinary variations.

Much trouble has been caused in various parts of the country by calculating water supplies from data and formulas compiled for use in places where the conditions are entirely different, and it would be of great service to water-works engineers if reliable data were available for all localities, and attempts to derive formulas for general application were abandoned.

Mr. Clifford. R. G. CLIFFORD, ASSOC. M. AM. SOC. C. E. (by letter).—Mr. Justin's attempt at furnishing a study of the relationship between precipitation and run-off which would lead to certain formulas applicable to watersheds of varying characteristics is most praiseworthy, and his deductions apparently apply within fair limits to the water-sheds considered.

In order to note certain danger marks in this mode of attack, the writer wishes to call attention to some of the data in the records furnished by Mr. Justin, and also to supplement his data with some from the far Western States, where conditions are somewhat different.

No equation, of course, is correct unless all the variables involved are introduced therein, but it may be that some of the conditions which change from year to year, or from one water-shed to another, are of such minor importance that their omission may not affect the result beyond the limit of accuracy desired, and it is this fact which has led the author to omit from his equation all but two of the eight variable conditions he mentions, namely, slope of water-shed and mean temperature.

Effect of Geology of Basin.—There are many cases where the geology of the basin has a marked effect on the run-off, as on the Pacific slope, where this element cannot be ignored in comparing one water-shed with another. The lava beds along the Pacific Coast, from the North Fork of the Feather River northward, are in themselves huge regulating reservoirs, which not only increase the summer flow, but actually tend to keep the total run-off for a whole season near the normal. For instance, the upper reaches of the North Fork of the Feather River for the season, 1910-11, gave a run-off of 36 in. with a rainfall of 59 in., or 61%, and during the next year 19 in. of run-off were produced by 23 in. of rainfall, or 82 per cent. An exponential equation averaging most nearly the records for 1905 to 1913 for this

water-shed would be $R = 2.2\ P^{0.7}$ (R being the run-off and P the precipitation). Mr. Clifford.

Farther south, along the Sierra water-sheds, where granite peaks have replaced the lava beds, the exponential varies up to $P^{1.5}$. For the South Fork of the Yuba River at the Spaulding Dam, the average exponent is unity, the equation being $R = 0.74\ P$.

Straight-Line Equations for Run-Off.—The various water-shed data drawn on logarithmic paper by Mr. Justin, having been replotted by the writer on natural-scale co-ordinate paper, it is found that a straight-line equation of the form, $R = a\ P + K$, will fit all of them just as well as the logarithmic curves, but, of course, the introduction of two variables only complicates matters when comparing one water-shed with another. It is necessary, however, to keep the exponent below the second power for the majority of cases, for there are a limited number of regions where the rainfall varies only 20% above or below the normal, as indicated by the data presented. On the Pacific slope the variation is from 40% below the average to 50% above, and the use of the second power in Mr. Justin's equation gives values of run-off in excess of the rainfall for the wetter years.

The very marked variation in total run-off for different years having the same rainfall should not be overlooked. The records from Lake Cochituate, with a small water-shed, show an extreme case, and if the run-off had been based on the years, 1865 to 1872, inclusive, a very different constant would have been used. Even the large water-shed above the new Croton Dam furnishes such a variety of points that no two men would be likely to choose just the same line as an average, and the years, 1872 to 1880, inclusive, would form the basis for a very different one. There are many reasons for this variation in run-off for the same precipitation. As the author points out, the ground-water conditions and inaccuracy in true average rainfall are probably important factors, but, in addition, there are such modifying elements as dry winds and relative packing of the snowfall; the former cutting down the snow in a remarkably short time, and the more solid the snow pack, the slower the melting and the greater the percolation.

The Mass-Curve.—It is with regard to applying any formula to monthly precipitation on different water-sheds, and thereby constructing a mass-curve to determine the necessary storage, that the writer feels that he cannot agree with Mr. Justin. In the first place, the exponential equation applied to the small monthly precipitations will not give the same yearly total as when applied to the total yearly precipitation, and it seems probable that the author intended merely to proportion the monthly rainfall to that for the whole year as computed from his formula. Now, although the total run-off for a season for different water-sheds may depend mainly on mean temperature and slope, yet the ratio of summer flow to winter flow may be absolutely

Mr. Clifford.

different. For instance, there are two branches of the same river, each having a water-shed of approximately 500 sq. miles and the same mean temperature, and yet the summer and winter flows of one have been, respectively, 560 and 10 000 cu. ft. per sec., though the second branch, in the same year, discharged 250 cu. ft. per sec. in summer and reached a maximum of 80 000 cu. ft. per sec. for the same winter flood as the other.

This is undoubtedly a peculiar case, and is principally due to the geological formation, but, to some extent, it is also due to the fact that there is a greater proportion of one water-shed at the higher elevation receiving the precipitation in the form of snow.

A study of the actual and computed mass-diagrams of the Croton water-shed is hardly a convincing argument in favor of this mode of determining the storage needed, unless a very long time average is used and it is feasible to build a reservoir large enough to effect regulations over long dry periods.

Considering the draft line used for the Croton water-shed, if in 1880 a dam had been constructed based on the rainfall formula, a depletion of 18 in. would have to be provided for; and, if 20 to 30% in excess were allowed, there would have been a safety factor, over actual conditions to date, of 60%, which would have been rather extreme.

In a great many power projects it is either physically impossible or very uneconomical to store much more water than comes from the average low years, and in such cases the essential feature is to know just how much auxiliary power is required for the extreme years and how often they come. The safest procedure, if no river data at all have been kept, is to study the run-off from the nearest available water-shed, having a similar geological drainage basin, on which records can be obtained, using Mr. Justin's corrections for slope and mean temperature. A percentage allowance for extreme conditions can then be based on a study of such long-time results as given on the Croton mass-curve.

To obtain the storage needed for power purposes, the writer has used an empirical formula based on the available data for the South Yuba River, which, for that particular water-shed, checks remarkably well for the 8 years available. This formula has not yet been applied to any other water-shed, and so would be most unsafe to use elsewhere. The basis for the formula is the length of the dry season and the precipitation. It pre-supposes that run-off records have been kept carefully for at least one year, the storage needed for any other year being in this particular case proportional to the length of dry season corrected inversely by one-third of the difference in percentage, from the average precipitation of the season immediately preceding. By using the equation, $R = 0.74\ P$ (applicable to this river), the high

points on a mass-curve can be located, and the low points can be plotted by means of the storage computed for each year, thus permitting of storage over long periods being found. The length of dry season is the most indefinite part of the proceeding, being the time of low stream flow, and is found approximately by records on other streams with similar geological formation, or, if a few years of monthly run-off and precipitation are available, by plotting these together and observing how the low-water flow follows the last heavy rains and picks up after the fall or winter storms. Mr. Clifford.

ROBERT E. HORTON, M. AM. SOC. C. E. (by letter).—Mr. Justin presents the formula: Mr. Horton.

$$C = 0.934\, S^{0.155}\, \frac{R^2}{T}$$

$$S = \frac{E \text{ max.} - E \text{ min.}}{A}$$

S = Average absolute slope of the drainage basin, in feet per foot;
E Maximum = Maximum elevation at any point in the drainage basin;
E Minimum = Minimum elevation, or elevation at outlet;
A = Area of drainage basin, in square miles;
R = Annual precipitation, in inches;
T = Mean annual temperature, in degrees, Fahrenheit;
C = Annual run-off depth, in inches.

He adopts the suggestion of the late George W. Rafter, M. Am. Soc. C. E., for the use of an exponential relation between rainfall and run-off. Mr. Rafter applied similar formulas to individual drainage basins, but as the slope, ground-water, and cultural conditions of each basin were more or less constant, it was not necessary for him to include these factors separately in his formula. The author's formula represents an attempt to derive a general relation between rainfall and run-off on different drainage basins, taking into account differences in mean temperature and slope, and he claims that this formula is applicable to the determination of the mean run-off throughout a series of years for streams in the Eastern United States. Some claim is also made that it is applicable to the determination not only in individual years but in individual months. The writer believes that the formula has a certain degree of value for practical application, but that its use should be confined to streams having relatively large drainage areas and with hydrological conditions similar to those prevailing in the larger streams of the New England and Eastern States.

Mr. Justin's study, though perhaps too largely statistical, contains many valuable suggestions. The writer does not feel that the formula given is entirely rational or that it will give reliable results in the one

Mr. Horton. instance where a practicing engineer commonly requires an estimate of the annual yield of a stream. Very many of the larger streams in the East have been accurately gauged. A large proportion of the public water supplies in the Eastern States are derived from small drainage basins which have not been accurately gauged. In the case of such basins, extensive storage is usually developed, and engineers are frequently called on to determine the minimum annual yield available to fill storage reservoirs. In such cases the mean annual yield for a period of years is of little use. Mr. Justin's formula does not appear to fulfill this requirement, because it certainly is not capable of general application to small drainage areas, say less than 25 sq. miles in extent. The absence of any factor in the formula to take into account differences in drainage basins as regards cultural and evaporation conditions is notable. Errors in calculations of the run-off for individual years, as suggested by the author, can be partly eliminated by starting the water year in each case with the ground-water and surface storage reduced to the same datum.

The author's formula is equivalent to the assumption that the annual evaporation loss is a direct and constant function of the rainfall or precipitation for areas having the same mean temperature. He presents a table of the calculated mean annual run-off from various drainage basins which shows surprisingly good agreement with his formula, and would appear to bear out the above conclusion. This conclusion is probably approximately correct for relatively large areas, each area containing a wide variety of different cultural conditions; the differences also make it evident that the annual evaporation loss may differ by considerable amounts when comparing small areas having the same rainfall, mean temperature, and slope, but differing widely as regards cultural conditions.

As a rule, in the case of streams in the Northeastern and New England States, about three-fourths of the annual run-off occurs during the winter or frozen season, when differences in soil and cultural conditions have but little effect. For example, given two drainage basins, each having 18 in. of run-off during the frozen season; the rainfall, slope, and temperature being the same in each, the evaporation loss during the vegetation season being 100% greater in one basin than in the other, giving, during the vegetation season, say, 6 in. annual run-off in one basin and 9 in. in the other, the difference in the total annual run-off for the two streams would be only $12\frac{1}{2}$ per cent. This example illustrates and explains the fact that, in the application of a formula of this kind, differences in soil and cultural conditions are much less important than might at first appear to be the case; it also illustrates the danger of wide errors appearing when an attempt is made to apply such a formula to individual months or even years.

Mr. Horton.

The author's formula for computing the mean slope of a drainage basin is very simple, but it does not appear to be sufficiently accurate. Furthermore, it appears probable that the variation in run-off, which, in his formula, the author attributes to slope, is not due to that alone, and, in fact, there may be other conditions not directly taken into account, having greater weight as regards their effect on annual run-off, which possibly may have masked the true effect of slope almost entirely in the case of the streams used by the author in deriving his slope formula. It is quite generally true that the flatter portions of a drainage basin are built-up, cleared, drained, and cultivated, whereas the steep slopes are more likely to be forest covered. In the author's method of derivation of the relation of slope to run-off, the effect of prevailing differences in cultural conditions between flat and steep areas would appear in the result as part of the effect of slope difference.

As regards the effect of forest conditions, the author appears to be of the opinion that it makes little difference in the annual run-off whether or not a drainage basin is forest covered. In the writer's opinion, Mr. Justin has omitted to mention the most important effect of forests in relation to run-off, as regards his formula. In fact, his conclusion, that deforesting a drainage basin would tend to reduce the low-water flow and at the same time greatly increase the floods, disproves his other contention. Assume, for example, the total dry-season flow of a stream to be 6 in.; let this be reduced to 3 in. by deforestation; also assume the flood period run-off with forest to be 16 in.; and let this be increased as a result of deforestation to 24 in. The net result will be an increase of 5 in. in the total annual run-off of the stream, or nearly 23%, due to deforestation. In the writer's opinion, this represents fairly a state of affairs which frequently occurs. However, the writer does not agree with Mr. Justin that the general or universal effect of deforestation is a decrease in the low-water flow of a stream; that may or may not be the result, depending largely on the permeability of the soil. For the Northern and Eastern States, the writer believes that the apparent increase in low-water flow of streams in the presence of forests is largely due to retardation of the melting of snow in the spring. This shortens the low-water season. On the other hand, the elaborate European forest experiments seem to prove conclusively that, taking into account intercepted rainfall, transpiration, and evaporation from the soil in the forest as compared with evaporation from the soil alone in the open, there is much greater loss of water during the growing season with forest than without. This proposition is confirmed by extensive European experiments showing that the ground-water table is generally lower under a forested area than under a cleared area.

With reference to the author's formula for the slope of a drainage basin, consider an inclined plane similar to Fig. 22. For purposes of

Mr. Horton.

illustration, let the slope of the plane be unity. For the three areas, *a b x o, c d x o*, and *e f x o*, Mr. Justin's formula gives slopes as follows:

Area, *a b x o*,

$$S = \frac{1 - 0}{\sqrt{1}} = 1$$

Area, *c d x o*,

$$S = \frac{2 - 0}{\sqrt{2}} = 1.42$$

Area, *e f x o*,

$$S = \frac{3 - 0}{\sqrt{3}} = 1.734$$

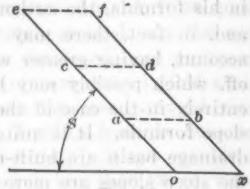

FIG. 22.

Thus it appears that, for an area on which the slope is actually constant, his formula gives a variation in slope of 75%; and although his formula is correct for square inclined planes, it is incorrect for planes which are not square. In other words, the apparent slope, as determined by his formula, is dependent on the shape of the area. For example: Compare square and circular plane areas having unit slope and unit area. For the square area, the author's formula gives $S = 1$, which is correct. For the circular area, it gives $X = 1.13$, an error of 13 per cent. For square areas which are not inclined planes, the author's formula may be seriously in error. For example: Consider the area shown in Fig. 23, which is assumed to represent a drainage basin of 9 sq. miles. According to his formula, the average slope of this basin is 116.67 ft. per mile. The actual average slope is 200 ft. per mile.

It appears that in the case of drainage basins deeply serrated by gullies, and long and narrow in form, the true slope may differ widely from that indicated by his formula. Such areas are very common in the hillside drainage of large valleys, such for example as the Upper Mohawk Valley, or the Finger Lakes, Flint Creek, and Cayuta Creek drainage basins, in the central part of New York State.

The writer suggests the following considerations as a basis for determining more accurately the slope of a drainage basin. The method given can be applied without difficulty or excessive labor in cases where the topographic maps of the U. S. Geological Survey are available. Referring to Fig. 24, consider the drainage basin crossed by contour lines representing equal differences in elevation. Let *a-b* represent the average distance between the contours *a* and *b*; let *D* equal the contour difference of elevation, in feet; then, as the map is a horizontal projection of the area,

$$\frac{D}{a\ b} = \tan. S$$

where *S* is the angle of the slope. The average slope of the strip between the contours, *a* and *b*, is equal to the contour difference, *D*,

divided by the average width of this strip, and a similar relation holds for the entire area. Mr. Horton.

Let W = the average horizontal distance between contours for the entire area;

L = Total length of contours on the area;

A = Area of the drainage basin.

$$\text{Then } W\,L = A$$

$$\tan. S = \frac{D}{W} = \frac{D\,L}{A}.$$

Where topographic maps are available, L may be determined by measuring with an opisometer the length of contours at 20-ft. or 40-ft. intervals, for small or flat areas, and the length of contours of 100-ft. to 500-ft. intervals for large or steep areas.

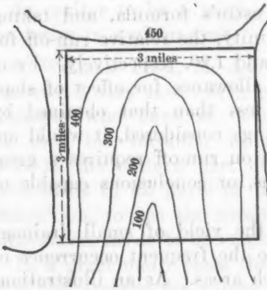

FIG. 23.

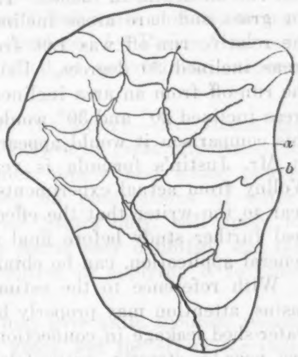

FIG. 24.

In the writer's opinion, the effect of slope on run-off is not measured entirely by the average slope of the topographic surface, but rather by the average slope of the lines which the water travels from the point where the rainfall strikes the ground to the point in the stream to which the area is taken. For an inclined plane, the average effective slope, if so it may be called, measured in this way, would not be the same as the average topographic slope of the surface. The effective slope at any point would be the elevation of the point divided by its distance from the point of measurement of the area. For geometrical figures, the mean distance of all points on an area from a point on the perimeter of the area can be determined from the surface integral of the area.* For example: In the case of a circular inclined plane, the shortest average distance which the water

* Byerly, "Integral Calculus," pp. 201-209.

Mr. Horton.

can travel to reach a point on the circumference would be 1.273 multiplied by the radius of the circle.

It would appear to the writer that the effect of slope on run-off can be better determined from a comparison of the run-off of small areas having similar topographic and cultural conditions throughout, than from the comparison of such large areas as have been used by Mr. Justin. In confirmation of this opinion, the elaborate and carefully conducted experiments of Wollny may be cited.* Throughout two growing seasons, 1882 and 1883, Wollny determined the run-off from areas of 1 sq. m. of argillaceous sand containing humus. In one series of experiments he used areas inclined 10°, 20°, and 30° to the horizontal and covered with a growth of grass. In another series of experiments he used similar inclined bare areas. The writer has reduced the total run-off for the period covered, April to September, inclusive, to equivalent run-off depth, in inches. Taking the mean run-off for the 2 years for grass and bare areas inclined 10° as a unit, Wollny found that the relative run-off was 1.66 from areas inclined 20°, and 2.40 from areas inclined 30 degrees. Using Mr. Justin's formula, and taking the run-off from an area inclined 10° as unity, the relative run-off for areas inclined 20° and 30° would be 1.12 and 1.20, respectively. From this comparison it would appear that the allowance for effect of slope in Mr. Justin's formula is very much less than that obtained by Wollny from actual experiments. All things considered, it would appear to the writer that the effect of slope on run-off requires a great deal further study before final conclusions, or conclusions capable of general application, can be obtained.

With reference to the estimation of the yield of small drainage basins, attention may properly be called to the frequent occurrence of water-shed leakage in connection with such areas. As an illustration: two near-by streams, accurately gauged by weirs under the writer's direction for several years, showed for the one a minimum run-off of about 250 000 gal. from a topographic drainage basin of 0.4 sq. mile, and for the other a minimum run-off of zero for a period of from 1 to 4 months in nearly every summer, with a drainage basin of 1.18 sq. miles. The topographic run-off from the two streams is probably about the same, but the effect of the inversion of water to one basin by water-shed leakage is sufficient to produce a considerably larger total annual run-off for that basin.

According to Mr. Justin's formula, the annual run-off varies inversely as the mean annual temperature. A method of estimating run-off involving the temperature as a factor was developed by Mr. C. C. Vermeule, a number of years ago. The thing which varies with the temperature is the evaporation loss, but the writer believes that the quantity evaporated is only indicated in a somewhat rough and irregu-

* *Forschungen auf dem Gebiete der Agricultur-Physik*, Prof. E. Wollny, Band XVIII, 1885, pp. 486, 516.

lar manner by the temperature. The evaporation loss is a function of the character and condition of vegetation and of the difference between the absolute vapor pressure in the atmosphere and the vapor pressure corresponding to the temperature of the evaporation surface. A number of years ago, Mr. Rafter pointed out that the evaporation loss is much more nearly constant than the rainfall. The reason for this does not appear to have been given. Apparently, however, the explanation lies in the fact that wet years are usually relatively cold and dry years are usually relatively hot. The evaporation also varies materially according to the distribution of the rainfall. In a hot dry year evaporation may be less than in a colder but wetter year, for the reason that during periods of extreme drought there is very little exposed surface, except in lakes or ponds, from which evaporation can take place. Mr. Horton.

The determination of evaporation losses by proportionate ratios deduced from measured evaporation from a free water surface, as suggested by Penck and more elaborately developed by Parker,* appears to the writer to be a more rational method of ascertaining evaporation losses in a given year.

J. WILLIAM LINK, M. AM. SOC. C. E. (by letter).—Mr. Justin has presented a very interesting paper on a subject of great importance to engineers who have to deal with water supply and water power, but that his formula, which is based on observations of water-sheds in the eastern part of the United States only, will apply to water-sheds in all parts of the country seems very doubtful, and his admonition, to use the formula with caution in applying it to other water-sheds, needs to be emphasized. Mr. Link.

In a great many cases the formula may give quite accurate results as to the average for a long period of years, but the errors for individual years may be quite large, and the young engineer or the engineer unfamiliar with handling rainfall and run-off data, should be extremely careful in its use. As an illustration of this point, reference to the author's diagram for the Sudbury water-shed will show that the actual run-off in several years varies as much as 8 or 10 in. from the results obtained by using the curve.

The author suggests that in the computation of run-off a discrepancy of 1 or 2 in. is not worth discussion. This may be true in some instances, though in considering the yield of a water-shed as related to water-power possibilities, even this discrepancy might be important; and, as the engineer figuring on water-power possibilities is usually more concerned with the individual year than with the average for a great many years, a discrepancy of 8 or 10 in. in the estimated run-off would often lead to serious consequences.

* "The Control of Water."

Mr. Link.

Of the author's diagrams, the two in which the observed data most nearly agree with the formula, are those for the Esopus and Schoharie water-sheds. In one case the observations cover only 5 years, and in the other only 4 years, and it might be suggested that the observed data in these cases are too few to furnish a satisfactory basis of comparison with a general formula.

As an illustration of the erratic nature of the relation between rainfall and run-off in some sections of the country, attention is called to a water-shed in California with an area of 250 sq. miles, on which the precipitation and run-off records have been kept with a considerable degree of accuracy. These data are shown in Table 6.

TABLE 6.

Years.	Annual precipitation, in inches.	Total run-off, in inches.	Run-off. Percentage of precipitation.
1906	32.33	3.72	11.54
1907	15.68	2.13	13.50
1908	18.69	0.81	4.34
1909	28.76	1.82	6.33
1910	12.61	1.06	8.40
1911	15.23	0.30	1.97

By an inspection of these data it will be seen that in 1907 there was the highest percentage of run-off, although the precipitation was less than one-half of that of the preceding year; and though the precipitation in 1911 was only slightly below that of 1907, the run-off was only one-seventh as great. Other water-sheds could be cited on which similar conditions obtain, but this one example will be sufficient to illustrate the point.

Mr. Justin lays particular stress on slope and mean annual temperature as the chief factors in determining the manner in which the relation between rainfall and run-off varies from one water-shed to another. The writer, however, would suggest that the geological formation and the distribution of rainfall throughout the year are factors of equal importance, and that if the relation of rainfall to run-off for different water-sheds, or for different years on the same water-shed, is ever reduced to an exact formula, such formula will have to take into account the distribution of rainfall throughout the year, as well as the other factors mentioned.

Mr. Finch.

J. K. Finch, Jun. Am. Soc. C. E. (by letter).—The writer simply desires to point out that the error involved in the method of estimating run-off from rainfall proposed by Mr. Justin is a function of the total time interval considered. Thus, if the formula be applied to the prob-

lem of determining the total run-off for several years from the rainfall for the corresponding period, the resulting error is small and may indeed be accounted for in many cases by the probable error in the rainfall data. If, on the other hand, the formula is applied to individual years, the resulting error is larger because the ground-water conditions may not be the same at the beginning and end of the year, and, when applied to individual months, the resulting run-off is, of course, in many cases absolutely different from the actual. Mr. Finch.

Now, the period to be considered, in estimating the storage for a given draft, is the length of time during which the reservoirs will be below high-water level. This would vary, with different localities, from a few months to such extremes as that mentioned by Mr. Le Conte for conditions near San Francisco, where 3 years were necessary; and on any water-shed it depends on the draft desired and the variations in run-off. Taking Mr. FitzGerald's* figures for the Sudbury watershed, for example, it is found that the period of depletion for drafts of from 200 000 to 650 000 gal. per sq. mile per day is 7½ to 10½ months, which approximates the average period during which the ground-water would be low. For 700 000 gal. and more, the period is 2 years and more. It should also be remembered that these figures are for the years of greatest drought, and that in the average year the periods would be much shorter.

One would expect, therefore, to obtain very close figures in the North Atlantic States for the storage required to maintain a certain draft by Mr. Justin's method, provided this draft was more than 700 000 gal. per sq. mile per day. For drafts of from 650 000 to 200 000 gal. one would find errors of increasing amount and for less than 200 000 gal., as the period of depletion is only a few months, the errors involved would be far in excess of the "20 to 30% in excess of the depletion shown by the mass-curve," which Mr. Justin states it is customary to use. In the average year the results would be in error by still greater quantities, although the average year is not the critical one for storage, and this feature is therefore not important.

The conclusion is, therefore, that Mr. Justin's method is reasonably satisfactory in the North Atlantic States for a few exceptional cases only, that is, where the storage possibilities of a water-shed have been developed to a great extent by building reservoirs, and a correspondingly large draft is to be expected. In the majority of cases economy does not justify such development, and, if the water is to be used for water-supply purposes, it is considered best to limit the period of depletion, and the drafts will generally be less than 200 000 gal. per sq. mile per day. For the solution of the average problem, therefore, the use of this method will be dangerous.

* *Transactions*, Am. Soc. C. E., 1892, Vol. XXVII, p. 268.

Mr. Finch. In these cases, where only a few months' storage is necessary, the method used must take into account ground-storage conditions, and, as far as the writer knows, Mr. Vermeule's method* gives the nearest approach to true run-off figures of any proposed thus far. Mr. Justin's general formula, introducing as it does the hitherto neglected effect of slope, combined with Mr. Vermeule's ground-storage curves, should give a very close approximation for estimating run-off from rainfall month by month.

Mr. Justin. JOEL D. JUSTIN, ASSOC. M. AM. SOC. C. E. (by letter).—That great caution is necessary in any attempt to predict the quantity of run-off from a water-shed, all engineers are agreed. That it is preferable to base calculations on the actual run-off, rather than on estimates founded on the rainfall of the water-shed is almost axiomatic. The methods and formulas presented in the paper are intended for use on water-sheds where run-off data are partly or totally lacking.

Given such a water-shed, one of two courses is open to the engineer desiring to build a storage reservoir: First, he may make a guess as to the run-off, taking it as a percentage of the rainfall, and being guided as much as possible by his judgment. Second, he may make a careful study of the conditions governing the relations of run-off to rainfall on the water-shed and on others having the same general characteristics, and, as the result of these studies, arrive at a run-off on which he may safely rely.

The formula derived by the writer is an attempt to reduce the second method to mathematical terms. Caution and judgment are necessary, of course, in using the formula, just as they are necessary in the use of formulas for, say, the design of a masonry dam. For instance, the writer would not attempt to apply the formula to the streams of California or Kansas without the possession of additional data.

Mr. Le Conte states that the formula gives the long average run-off. This is incorrect. The formula gives equally well the run-off for any particular year. In order to prove this, Tables 4 and 5 were prepared, showing that, in nearly all years, the agreement between the run-off computed by the formula and that recorded was remarkably close. It was even shown that usable mass-curves could be built up by the use of the formula. Mr. Le Conte points to a case in California where for 3 successive years there was no run-off. It is probable that the formula, if applied to this water-shed, would for these 3 years give such a small run-off as to be negligible.

Even on water-sheds where run-off data are available, it is necessary to use them with caution, as measurements of flow may be very inaccurate. The whole subject is one which does not permit of precision.

* Geological Survey of New Jersey, Vol. III, 1894.

Mr. Justin.

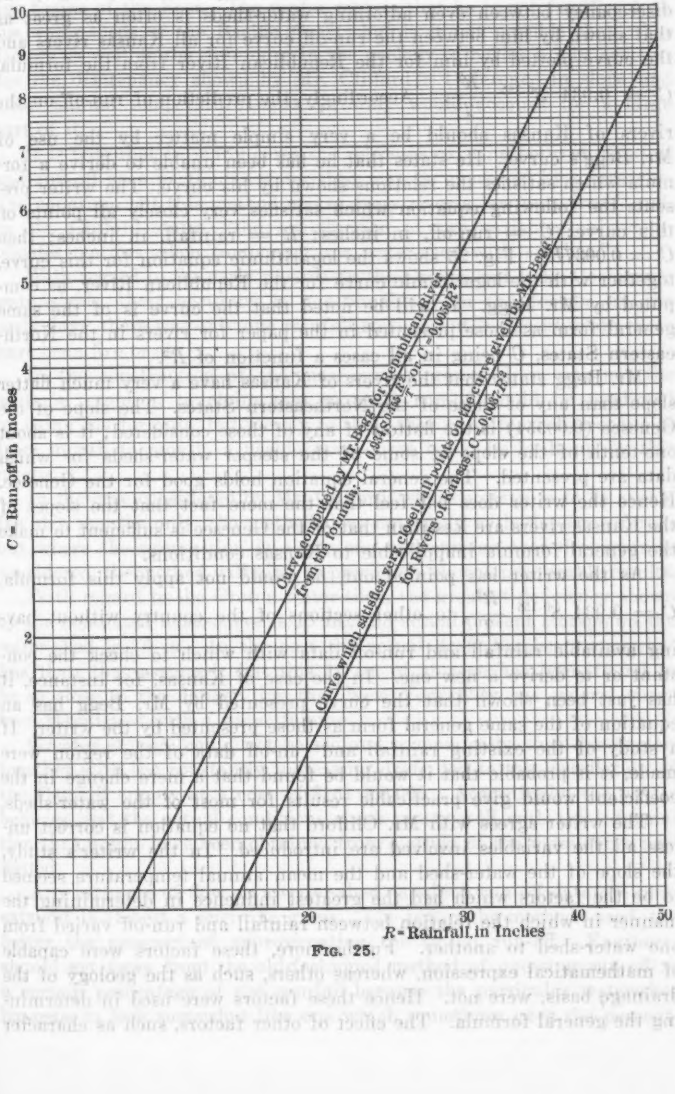

FIG. 25.

Mr. Justin.

On Fig. 21 Mr. Begg gives a run-off curve for the rivers of Kansas, and states that nearly all points fall on or near this curve. This is a condition which is truly remarkable. In other parts of the country the discrepancy between even adjoining water-sheds is often as great as that shown by him between the run-off curve for all Kansas rivers and the curve plotted by him for the Republican River from the formula, $C = 0.934\ S^{0.155}\ \frac{R^2}{T}$. Accordingly, the prediction of run-off on the rivers of Kansas should be a very simple matter by the use of Mr. Begg's curve. He states that he has been unable to derive a formula which satisfies the relations shown by his curve. The writer presents the following equation which satisfies very closely all points on this curve: C = run-off, in inches; R = rainfall, in inches; then $C = 0.0037R^2$. Fig. 25 shows the logarithmic equation for this curve, together with the logarithmic curve for the Republican River, as computed by Mr. Begg. It will be noted that the curve is of the same general form as those presented in the paper for rivers in the Northeastern States, C being in all cases a function of R^2.

Mr. Begg states that the rivers of Kansas have a very much flatter slope than any of those of the Northeastern States. The slope of the Genesee (0.00554) is the flattest of any of those considered; it is about one-tenth of the slope of some of the steeper water-sheds for which data are presented. The general equation holds good for the Genesee. Hence the writer does not feel that the mere fact that the slopes of the Kansas rivers are less than that of the Genesee is sufficient to make the general formula inapplicable to Kansas conditions.

As the writer has pointed out, he would not apply this formula, $C = 0.934\ S^{0.155}\ \frac{R^2}{T}$, to other sections of the country without having available rainfall and run-off data with which to check the constant or to derive a new one. In the case of Kansas, for instance, it has just been shown that the curve presented by Mr. Begg has an equation of the same general form as those presented by the writer. If a study of the existing rainfall and run-off data of the region were made, it is probable that it would be found that a mere change in the coefficient would give practicable results for most of the water-sheds.

The writer agrees with Mr. Clifford that no equation is correct unless all the variables involved are introduced. In the writer's study, the slope of the water-shed and the mean annual temperature seemed to be the factors which had the greatest influence in determining the manner in which the relation between rainfall and run-off varied from one water-shed to another. Furthermore, these factors were capable of mathematical expression, whereas others, such as the geology of the drainage basis, were not. Hence these factors were used in determining the general formula. The effect of other factors, such as character

of vegetation, extent of forest covering, prevailing winds, relative humidity, barometric pressure, etc., seems to be well within the limit of accuracy of the existing data. At least this is the case with the drainage basins of the East. The writer regrets that he is not familiar with the water-sheds of the Pacific Coast; but is it not possible that other factors as well as the difference in the geology of basins might account for the discrepancy shown by Mr. Clifford? Difference in slope and mean annual temperature most certainly would account for a large part of it. Mr. Justin.

It is true that in many cases the relations existing between rainfall and run-off on a particular water-shed may be expressed by a straight-line equation, but this method makes every river a law unto itself, and, as Mr. Clifford states, "the introduction of two variables only complicates matters when comparing one water-shed with another."

With regard to the early records on the Croton and Lake Cochituate water-sheds, their accuracy is questionable. On the former, in the early days, there was only one rainfall station, but in recent years there have been five or six.

In the construction of the mass-curves presented, it was not the writer's intention to claim that monthly run-off could be predicted by using his formula, but merely to show that in spite of discrepancies from month to month, a usable mass-curve could be built up by this means.

In the case considered by Mr. Clifford, where storage is to be over a few dry months only, the method does not apply with the same force; but where the proposition is a big one and storage over dry years is considered, the method will give, as previously shown, practicable results.

With regard to the Croton water-shed, the greatest deficiency shown by the computed mass-curve is 18 in., the actual present storage on the water-shed is 16 in. In the past the actual draft has been somewhat less than that assumed; but this 16 in. of storage has been found to be so close to the danger line that New York City has several times been threatened with a water famine.

Greater storage could not be secured economically, and this factor, together with the constantly increasing draft, led to the installation of the Catskill supply at a cost of $161 000 000. Accordingly, the writer believes that the actual conditions check pretty well with the information that might have been obtained from a study of the mass-curve presented.

Any estimate of flow on a water-shed on which run-off data are non-existent is at best a scientific guess. The better the methods used, the better the prospect of approximating the actual run-off. Engineers should get away from the old-fashioned method of guessing run-off as a certain percentage of the rainfall because the particular water-shed happens to look somewhat like one which sometimes gave the percent-

Mr. Justin.

age of run-off guessed at. They should attempt to predict run-off by a careful study of all the data available from surrounding water-sheds. It was as an aid in such a study that the present formula was derived.

Mr. Horton states that the writer's formula is certainly not capable of general application to small drainage areas. On what facts does he base this conclusion? In the paper it was shown that the formula applied equally well to the Connecticut, with its 10 000 sq. miles of water-shed, and to the Sudbury, with its water-shed of 75 sq. miles. What is there in a water-shed containing from 15 to 25 sq. miles to make it inherently different from one containing from 70 to 10 000 sq. miles? Why should water-sheds be divided into two classes: those containing more and those containing less than 25 sq. miles?

The writer regrets that he did not have available more data on the slope, mean annual temperature, rainfall, and run-off of small water-sheds. He is confident, however, that, given equally accurate data on slope, temperature, and rainfall, run-off can be predicted by the formula just as accurately for a small water-shed as for a large one. The difficulty is in obtaining these data. The slope is easily ascertained, but the nearest station having rainfall and temperature records may be many miles distant from the small water-shed in question. If such data are used, and especially if they are used without some logical method of correction, the formula, of course, may give very misleading results.

Mr. Horton cites a water-shed of 0.4 sq. mile, which had a considerable minimum run-off, though an adjoining water-shed of 1.18 sq. miles had a minimum flow of zero. The same thing happens on larger water-sheds, and must be looked out for in the application of any formula. For instance, the writer knows of a stream, which, when measured at a gauging station, where the bottom was ledge rock, gave considerably higher results in midsummer than when measured at another gauging station only a short distance away, where the bottom was a gravel deposit of considerable depth and extent. This matter of water-shed leakage cannot be covered by any formula; but it should not make any trouble for the engineer who applies the formula to a given water-shed, after having made a study of the existing conditions.

As regards cultural and soil conditions, the writer believes that the slope is a fair, if rough, index to these conditions. Thus, as Mr. Horton states, the flat water-shed is pretty sure to consist largely of cultivated lands and meadow with a deep soil covering; and a very steep water-shed is pretty sure to be quite heavily forested and have a light soil covering.

The criticism made by Mr. Horton of the writer's simple method of obtaining slope is merited, from a mathematical standpoint, and he freely acknowledges that the method suggested by Mr. Horton would give a truer index of the slope. Of course, it is a matter of opinion

as to whether or not excessive labor is involved in Mr. Horton's method of deriving slope. The writer believes that most engineers would consider excessive this labor of measuring all the contours on a watershed and obtaining the average distance between them. On several water-sheds the writer has tried to obtain a value for average slope by weighting the average slope between contours according to the area between them, and has found the work very great; and, as it led to no increase in final accuracy, he determined that, even if he did adopt such a method, probably no one else would ever do so. Mr. Horton's method is the more logical, but unless he can show that it would lead to a more accurate prediction of run-off, it would be a mere waste of time to use it. Mr. Justin.

Mr. Horton points out several ideal cases in which the slope indicated by the writer's method would differ from the true slope by from 13 to 75 per cent. If Mr. Horton were considering actual watersheds, the writer believes that he would find it difficult to discover a deviation as great as that represented by the second figure. However, even if this deviation were large, it would not be material, for it requires a change of about 100% in slope to make any material change in the relations of rainfall to run-off.

Just how unimportant Mr. Horton's objection to the writer's method of obtaining slope is, may be shown by the following illustration: In Table 1, the mean annual temperature for the Hudson is 41.9 and for the Connecticut 42, but the slope of the Hudson is 0.0149 and that of the Connecticut 0.0117, a difference of more than 20 per cent. In the table, the values of K for these two water-sheds are, respectively, 0.0118 and 0.0117. In other words, in an actual case, where other conditions remain the same, a difference in slope of 20% causes a difference in computed run-off of less than 1 per cent. The effect of slope is not felt until the change becomes comparatively large. The slopes of the steepest water-sheds considered in the paper are ten times as great as those of the flattest.

Mr. Finch points out that, in the ordinary storage proposition, storage for a few months only is considered, and he believes that it would be dangerous to apply to such a case the writer's method of building up a mass-curve by the formula.

That the method will give more accurate results where storage is to cover the greater part of one or more years, the writer believes, but that it would be dangerous to apply it to a case where only a few months' storage is desired, he does not believe, provided, of course, that due caution and good judgment are used.

If there are no run-off data, some method of determining the size of the reservoir must be found, and the writer believes that, even for brief periods of storage, this method will give more reliable results than can otherwise be obtained.

Mr. Justin.

Mr. Link objects to the use of the short term of the Esopus and Schoharie records in obtaining the general formula. The record on the Esopus, because of the extreme accuracy with which it was obtained, is entitled to equal or even greater weight with the long-term and far less accurate records on the Croton and Sudbury. On the Esopus as many as 13 rainfall stations were maintained on a watershed of 240 sq. miles, and the run-off was measured with a specially constructed concrete weir. On part of the Sudbury and Croton records, the rainfall was obtained from a single station; later, other stations were added. The discrepancies pointed to in the Sudbury records are the only ones of large magnitude in the entire paper, and are very probably due to the condition stated.

With regard to Mr. Link's statement that a discrepancy of 1 or 2 in. is material, it may be said that the present methods of measurement of rainfall do not justify the expectation of anything closer in the average case. Frequently, on large water-sheds, the average is one rainfall station to 1 000 sq. miles.

The behavior of the California water-shed cited by Mr. Link is certainly very erratic; but a large part of the discrepancy may be explained, perhaps, by variations in the ground-water storage. If Mr. Link had been able to divide his periods into water years, at the end of each of which the ground-water level was practically the same, probably it would be found that periods having the same precipitation would also have practically the same run-off. It would also be worth while to look into the accuracy of the precipitation and run-off data in a case of this kind.

AMERICAN SOCIETY OF CIVIL ENGINEERS

TRANSACTIONS

Paper No. 1289

PROGRESS REPORT OF THE SPECIAL COMMITTEE ON CONCRETE AND REINFORCED CONCRETE.*

I. Introduction.

1.—Appointment and Work of Committee.

In 1903 and 1904 Special Committees were appointed by the American Society of Civil Engineers, American Society for Testing Materials, American Railway Engineering and Maintenance of Way Association, and the Association of American Portland Cement Manufacturers, for the purpose of investigating current practice and providing definite information concerning the properties of concrete and reinforced concrete and to recommend necessary factors and formulas required in the design of structures in which these materials are used. The history of the appointment of the committees is as follows:

At the Annual Convention of the American Society of Civil Engineers, held at Asheville, N. C., June 11th, 1903, the following resolution was adopted:

"It is the sense of this meeting that a Special Committee be appointed to take up the question of concrete and steel-concrete, and that such committee co-operate with the American Society for Testing Materials, and the American Railway Engineering and Maintenance of Way Association."

Following the adoption of this resolution, a Special Committee on Concrete and Steel-concrete was appointed by the Board of Direction on May 31st, 1904. At the Annual Meeting, held January 18th, 1905, the title of this Special Committee was, at the request of the

*Presented to the Annual Meeting, January 15th, 1913.

Committee, changed to "Special Committee on Concrete and Reinforced Concrete." This Special Committee held its first meeting at Atlantic City, N. J., June 17th, 1904, and effected an organization; Mr. C. C. Schneider was appointed Chairman and Mr. J. W. Schaub, Secretary. Mr. Schneider resigned from the Committee on January 3d, 1911, and the Board of Direction, on January 31st, 1911, appointed Mr. J. R. Worcester as Chairman. On the resignation of Mr. J. W. Schaub, Mr. Richard L. Humphrey was appointed Secretary on October 11th, 1905.

At the first meeting of the Committee it was decided to co-operate with similar committees which had been appointed by the American Society for Testing Materials and the American Railway Engineering and Maintenance of Way Association through the organization of a Joint Committee on Concrete and Reinforced Concrete.

Subsequent meetings of the Committee were held at New York in January, 1906, 1907, 1909, 1910, 1911, and 1912; on December 10th, 1907; on March 1st, April 3d, May 1st, 1911, and on November 20th, 1912; at Philadelphia in December, 1908; and at Chicago in June, 1910. The Committee was also represented at all the meetings of the Joint Committee.

At the annual meeting of the American Society for Testing Materials, held on July 1st, 1903, at the Delaware Water Gap, the following resolution was unanimously adopted:

"That the Executive Committee be requested to consider the desirability of appointing a committee on 'Reinforced Concrete', with a view of co-operating with the committees of other societies in the study of the subject."

At the meeting of the Executive Committee of the American Society for Testing Materials, held on December 5th, 1903, a special committee on "Reinforced Concrete" was appointed.

The American Railway Engineering and Maintenance of Way Association appointed a Committee on Masonry on July 20th, 1899, with instructions, as a part of its duties, to prepare specifications for concrete masonry. A preliminary set of specifications for Portland cement concrete was reported to and adopted by the Association on March 19th, 1903. At the meeting held in Chicago on March 17th, 1904, the Committee on Masonry was authorized to co-operate with the Special Committee on Concrete and Reinforced Concrete of the American Society of Civil Engineers, and, following this action, a special sub-committee was appointed.

At a meeting of the several special committees representing the above-mentioned societies, held at Atlantic City, N. J., on June 17th, 1904, arrangements were completed for collaborating the work of these several committees through the formation of the Joint Committee on

Concrete and Reinforced Concrete. Mr. C. C. Schneider was elected temporary chairman and Professor A. N. Talbot temporary secretary. The proposed plan of action of the Special Committee of the American Society of Civil Engineers was outlined, involving the appointment of sub-committees on Plan and Scope, on Tests, and on Ways and Means.

The Joint Committee, at its first meeting, invited the Association of American Portland Cement Manufacturers to join in its deliberations through a committee appointed for the purpose.

The Joint Committee, at meetings at St. Louis in October, 1904, and at New York in the following January, perfected its organization by the adoption of rules and the choice of Mr. C. C. Schneider as Chairman, Mr. Emil Swensson, Vice-Chairman, and Mr. J. W. Schaub, Secretary. Later, on the resignation of Mr. Schaub, Mr. Richard L. Humphrey was chosen Secretary. Sub-committees on Plan and Scope, on Tests, and on Ways and Means were appointed.

The Joint Committee, as thus organized, consisted of the following members:

OFFICERS.

Chairman.—C. C. SCHNEIDER.
Vice-Chairman.—EMIL SWENSSON.
Secretary.—RICHARD L. HUMPHREY.

MEMBERS.

American Society of Civil Engineers (Special Committee on Concrete and Reinforced Concrete):

Greiner, J. E., Consulting Engineer, Baltimore and Ohio Railroad, Baltimore, Md.
Hatt, W. K., Professor of Civil Engineering, Purdue University, Lafayette, Ind.
Hoff, Olaf, Vice-President, Butler Brothers, Hoff and Company, New York, N. Y.
Humphrey, Richard L., Consulting Engineer; Engineer in Charge, Structural Materials Testing Laboratories, U. S. Geological Survey, Philadelphia, Pa.
Lesley, R. W., President, American Cement Company, Philadelphia, Pa.
Schaub, J. W., Consulting Engineer, Chicago, Ill.
Schneider, C. C., Consulting Engineer, Philadelphia, Pa.
Swensson, Emil, Consulting Engineer, Pittsburgh, Pa.
Talbot, A. N., Professor of Municipal and Sanitary Engineering, in Charge of Theoretical and Applied Mechanics, University of Illinois, Urbana, Ill.
Worcester, J. R., Consulting Engineer, Boston, Mass.

American Society for Testing Materials (Committee on Reinforced Concrete):

Fuller, William B., Consulting Engineer, New York, N. Y.

Heidenreich, E. Lee, Consulting Engineer, New York, N. Y.

Humphrey, Richard L., Consulting Engineer; Engineer in Charge, Structural Materials Testing Laboratories, U. S. Geological Survey, Philadelphia, Pa.

Johnson, Albert L., Consulting Engineer, St. Louis, Mo.

Lanza, Gaetano, Professor of Theoretical and Applied Mechanics, Massachusetts Institute of Technology, Boston, Mass.

Lesley, R. W., President, American Cement Company, Philadelphia, Pa.

Marburg, Edgar, Professor of Civil Engineering, University of Pennsylvania, Philadelphia, Pa.

Mills, Charles M., Principal Assistant Engineer, Philadelphia Rapid Transit Company, Philadelphia, Pa.

Moisseiff, Leon S., Engineer of Design, Department of Bridges, New York, N Y.

Quimby, Henry H., Assistant Engineer of Bridges, Bureau of Surveys, Philadelphia, Pa.

Taylor, W. P., Engineer in Charge of Testing Laboratory, Philadelphia, Pa.

Thompson, Sanford E., Consulting Engineer, Newton Highlands, Mass.

Turneaure, F. E., Dean of College of Mechanics and Engineering, University of Wisconsin, Madison, Wis.

Wagner, Samuel Tobias, Assistant Engineer, Philadelphia and Reading Railroad, Philadelphia, Pa.

Webster, George S., Chief Engineer, Bureau of Surveys, Philadelphia, Pa.

American Railway Engineering Association (Sub-Committee on Reinforced Concrete):

Beckwith, Frank, Engineer of Bridges and Structures, Lake Shore and Michigan Southern Railroad, Cleveland, Ohio.

Boynton, C. W., Inspecting Engineer, Cement Department, Illinois Steel Company, Chicago, Ill.

Cunningham, A. O., Chief Engineer, Wabash Railroad, St. Louis, Mo.

Scribner, Gilbert H., Jr., Contracting Engineer, Chicago, Ill.

Swain, George F., Professor of Civil Engineering, Massachusetts Institute of Technology, Boston, Mass.

Association of American Portland Cement Manufacturers (Committee on Concrete and Steel Concrete):

Fraser, Norman D., President, Chicago Portland Cement Company, Chicago, Ill.

Griffiths, R. E., Vice-President, American Cement Company, Philadelphia, Pa.

Hagar, Edward M., Manager, Cement Department, Illinois Steel Company, Chicago, Ill.

Newberry, Spencer B., Manager, Sandusky Portland Cement Company, Sandusky, Ohio.

Since organization, the following changes have occurred in the *personnel* of the Joint Committee:

J. W. Schaub, died March 30th, 1909.
C. C. Schneider, resigned January 3d, 1911.
Ernest R. Ackerman, resigned.
T. J. Brady, resigned.
Frank Beckwith, resigned.
A. O. Cunningham, resigned.
George F. Swain, resigned.

The following representatives of the American Railway Engineering Association have since been appointed:

Thompson, F. L., Engineer of Bridges and Buildings, Illinois Central Railroad, Chicago, Ill.

Alternates:

Hotchkiss, L. J., Assistant Bridge Engineer, Chicago, Burlington and Quincy Railroad, Chicago, Ill.

Prior, J. H., Assistant Engineer, Chicago, Milwaukee and St. Paul Railway, Chicago, Ill.

Schall, F. E., Bridge Engineer, Lehigh Valley Railroad, South Bethlehem, Pa.

Tuthill, Job, Assistant Engineer, Cincinnati, Hamilton and Dayton Railway, Cincinnati, Ohio.

At a meeting of the Joint Committee held at Atlantic City, N. J., on June 30th, 1911, Mr. J. R. Worcester was elected Chairman.

Meetings of the Joint Committee have been held as follows:

June 17th, 1904, at Atlantic City, N. J.
Oct. 4th, 5th, 6th, 1904, at St. Louis, Mo.
Jan. 17th, 1905, at New York, N. Y.
June 21st, 1905, at Cleveland, Ohio.
June 30th, 1905, at Atlantic City, N. J.
Oct. 11th, 1905, at New York, N. Y.

Dec. 14th, 1905, at New York, N. Y.
June 21st, 1906, at Atlantic City, N. J.
Dec. 13th, 1906, at New York, N. Y.
Jan. 15th, 1907, at New York, N. Y.
March 7th, 1907, at New York, N. Y.
March 18th, 1907, at Chicago, Ill.
June 21st, 22d, 1907, at Atlantic City, N. J.
Dec. 10th, 1907, at New York, N. Y.
Oct. 27th, 28th, 1908, at New York, N. Y.
Dec. 9th, 10th, 11th, 1908, at Philadelphia, Pa.
June 30th, 1911, at Atlantic City, N. J.
Nov. 20th, 1912, at New York, N. Y.

At the meeting of the Joint Committee at St. Louis in October, 1904, it was determined to arrange tests at such technological institutions as were provided with the requisite facilities and were willing to co-operate, the Committee, through its sub-committee on Ways and Means, to provide materials, and through its sub-committee on Tests, to consult as to lines of testing and to advise as to methods. The following ten institutions, Case School of Applied Science, Columbia University, Cornell University, University of Illinois, State University of Iowa, Massachusetts Institute of Technology, University of Minnesota, Ohio State University, Purdue University, and University of Wisconsin, undertook a preliminary series of tests, and carried them through, in due time reporting their results to the Committee.

Through the inability of the Committee to do as much as it had hoped by way of furnishing uniform materials for these tests and exercising a proper supervision, the results were not as serviceable as they would have been if the full plans had been carefully carried out; but much important information was received in this manner, and the Committee desires to express its gratitude to the professors and students who assisted so kindly in this work.

The results were collated and edited by the Secretary of the Committee at the Structural Materials Testing Laboratories of the U. S. Geological Survey, St. Louis, and the results, in typewritten form, were circulated among the members of the Committee. It was hoped that they might be published by the Geological Survey as a Bulletin, but in that the Committee was disappointed, though some of the results have been published in bulletins and papers issued by their authors.

In June, 1905, the U. S. Geological Survey proposed to co-operate with the Joint Committee to the extent of placing the tests made at the St. Louis Laboratory at its service and allowing the Committee the privilege of advising as to what tests of concrete and reinforced concrete should be conducted there. This co-operation was welcomed by the Committee, and was brought about by the fact that the Secretary

of the Committee, who was also the Chairman of the sub-committee on tests, was in charge of the St. Louis Laboratory.

During the five years in which the investigations of structural materials were in progress under the direction of the United States Geological Survey, a large amount of data relating to concrete and reinforced concrete was obtained. These investigations have included the survey of the constituent materials of concrete, such as sands, gravels, and crushed stone, in the various parts of the United States, covering their strength as mortars or concretes in various consistencies and proportions.

A number of series of tests of plain and reinforced concrete beams was made, covering the influence of character of aggregates, proportions and age, percentage of reinforcement, the effect of the variation in span relative to the depth, methods of anchorage of the reinforcement, etc., upon strength. A study was made of the effect of the personal equation in tests of beams, made by three construction companies operating in St. Louis, and by the employees of the testing laboratory. Tests covering bond, shear, compressive strength, and weight per cubic foot, for various classes of aggregates, were made.

Among other investigations were tests of reinforced concrete slabs of 12 ft. span, supported at two and four edges, strength and other properties of cement hollow building blocks, of the permeability of cement mortars and concretes, value of various water-proofing and damp-proofing preparations, effect of alkali and sea water on cement mortars and concretes, the fire-resistive properties of concrete and other structural materials, and these have been made and published, in part.

The collation and study of the data obtained were seriously handicapped through lack of funds available for this purpose, the large part of the appropriation being devoted to work urgently required by the various Government Bureaus. Of the annual Government appropriation of \$100 000, there was never available more than \$15 000 per annum for the investigation of concrete and reinforced concrete, and for several years the amount did not exceed \$5 000 a year. None of this was available for the publication of results, and the allotment from the funds provided for all Government printing was wholly inadequate for the purpose.

On June 30th, 1910, Congress transferred this work to the Bureau of Standards, together with the data collected. It is understood that arrangements have been made by which the data of the tests will be published as rapidly as conditions permit.

The Committee has had the benefit of the results of investigations by a number of laboratories, some of which were under the direct supervision of its members. The extent and varied character of the

tests, and their interpretation by those in charge, made them of especial value to the Committee.

The Committee also has had the advantage of investigations made in foreign laboratories.

At a meeting of the Joint Committee at Atlantic City, on June 30th, 1905, it was decided to divide among its members the work of collating and digesting the results of all available tests on concrete and reinforced concrete, and, in pursuance of this resolution, sub-committees were appointed on the following subjects:

Historical.
Aggregates, Proportions and Mixing.
Physical Characteristics, Water-proofing, etc.
Strength and Elastic Properties.
Simple Reinforced Concrete Beams.
T-Beams, Floor Slabs, etc.
Columns and Piles.
Fire-resistive Qualities.
Failures of Concrete Structures.
Arches.

A large amount of work was done by these sub-committees, and extensive reports were submitted by most of them. These reports were typewritten in manifold and circulated among the members of the Joint Committee, and were of great value to the Committee in arriving at its conclusions.

The Sub-Committee on Ways and Means raised by subscription about $8 000, which was used for preliminary investigations and expenses incident to printing its report and carrying on the work of the Committee. The Committee desires to express its appreciation for contributions and for donations of materials.

Even with this support, the field of activity of the Committee has been limited in scope, and it has been unable to undertake investigations of its own.

In 1908 the Committee began the preparation of the Progress Report which was submitted to the Society in January, 1909. A preliminary outline was prepared by the Secretary and submitted to the Committee in October. On October 27th, a meeting of the Joint Committee was held at New York, at which the report was discussed paragraph by paragraph, and chapters were referred to sub-committees and carefully revised during the following three weeks. The whole, as thus amended and revised, was again submitted in print to a full meeting held at Philadelphia, on December 9th, 10th, and 11th, and again was gone over in great detail. As a result of those two meetings, a considerable amount of matter, which it was at first intended to include, was omitted on account of slight disagreements as to its form

and lack of time to work it into satisfactory shape, and to this fact may be attributed some of the criticisms which have been elicited. It is hoped, in this report, to avoid these objections.

In the spring of 1911 the work of revising the 1909 Progress Report was taken up, and a number of meetings were held. The discussions submitted to the American Society of Civil Engineers and subsequent papers relating to the same subject were carefully considered, and differences of opinion between members of the Committee were threshed out.

Through the co-operation of the societies represented on the Joint Committee, the report was again put in type, and the necessary editions were printed for the use of the members of the Committee, the last bearing the date of August 1st, 1911. In the form thus reached, the report remained until November 20th, 1912, when the Committee again met in New York and gave the final review needed to bring it into the shape in which it is now presented.

2.—Historical Sketch of Use of Concrete and Reinforced Concrete.

In considering the history of concrete and reinforced concrete, a distinction should be made between the two. The use of concrete extends back to long before the Christian era—on the other hand, the art of reinforced concrete is in its infancy.

The use of concrete by the ancient Romans was due to the discovery of the fact that volcanic ash or puzzolan, when mixed with slaked lime, made a cement possessing hydraulic properties. The durability of this work of the Romans was due largely to favorable climatic conditions and the character of the cement used.

From the downfall of the Roman Empire to the last half of the Eighteenth Century the manufacture of cement seems to have been discontinued. The Roman cement mortars and concretes surviving the ravages of the elements became so hard that the cement acquired a reputation that led the early experimenters of the Eighteenth Century to seek to recover this supposedly lost Roman art. Evidently, no concrete was used during this period, for the necessity of simultaneous induration in the interior and exterior of the mass prevents the use of lime alone in concrete, and requires the use of some material having hydraulic qualities. This fact limited the use of concrete to regions where hydraulic limes and cements were to be found.

In 1756 Smeaton discovered that an argillaceous limestone produced a lime that would set and harden under water, but no immediate appreciation of this knowledge appears to have resulted.

Natural cement was first manufactured by Parker in 1795, as a result of an attempt to equal or excel Roman cement, and in 1796 he took out an English patent. Natural cement was first produced in America in 1818, and for a long time was the principal cement used.

With the introduction of Portland cement, and the reduction in the cost of manufacture, there has been a gradual substitution of Portland for natural cement. The production of natural cement reached a maximum of nearly 10 000 000 bbl. in 1899 and gradually decreased to about 9 000 000 bbl. in 1911.

The art of manufacturing Portland cement was discovered in 1811 by Joseph Aspdin, and patented by him in 1824. He called this cement "Portland" by reason of its resemblance to a building stone obtained from the Isle of Portland, off the coast of England. Up to 1850 very little progress was made in the manufacture of this cement in England. Since 1855, however, the increase in the production in Europe has been steady, and its superiority has led to a gradually increasing use in such structures as require concrete in mass, as foundations, fortifications, sea-walls, docks, locks, etc. While Portland cement was first manufactured in 1824, and was produced in 1871 by David O. Saylor, at Coplay, Pa., and by Thomas Millen, at South Bend, Ind., it was not until the early Eighties that it was manufactured to any extent in America. From that time on, the production has rapidly increased, reaching the enormous total of nearly 80 000 000 bbl. in 1911. This increase in production has been largely stimulated by the reduction in cost of Portland cement through the perfection of the American methods, the introduction of reinforced concrete, and the extensive use of cement during the last few years.

In 1850 Joseph Gibbs obtained a British patent for casting solid walls in wooden moulds, and in 1897 C. W. Stevens obtained a patent for making artificial cast stone with concrete. It is not clear, however, that these inventors were the first to use the material in a similar way.

The origin of the idea of increasing the load-carrying capacity of concrete by reinforcing it with metal embedded in it is generally attributed to Joseph Monier, a French gardener, who used a wire frame or skeleton embedded in concrete in the construction of flower pots, tubs, and tanks, in 1867, and for which he obtained the first patent of the kind in the same year. This was not the first use of the material, however, as Lambot constructed a boat of reinforced concrete in 1850, which was exhibited at the Paris Exposition in 1853. He took out an English patent in 1855.

In France, in 1861, François Coignet applied the principles of reinforced concrete in the construction of beams, arches, pipes, etc., and with Monier exhibited some of their work at the Paris Exposition of 1867. Coignet also took out an English patent in 1855. In England, in 1854, W. B. Wilkinson took out a patent for a reinforced concrete floor. In America, Ernest L. Ransome used metal in combination with concrete as early as 1874, and W. E. Ward erected, in 1875, at Port Chester, New York, a house built entirely of reinforced concrete.

Monier, while not the first to apply it, obtained the first patents for reinforced concrete, the German and American rights of which he disposed of to G. A. Wayss and Company in 1880. Wayss and J. Bauschinger, shortly after, began the tests on this material which were published in 1887.

Thaddeus Hyatt, an American engineer, employed David Kirkaldy of London to make the experiments on reinforced concrete which Hyatt published in 1877. The theories of Hyatt were applied in a practical way to building construction in 1877 by H. P. Jackson, of San Francisco.

In America, Ransome, between 1874 and 1884, constantly increased his application of metal reinforcement consisting of old wire rope and hoop iron, gradually realizing the necessity for using it with a greater regard for its proper position in the mass, and in 1884 took out the first patent for a deformed bar. Prior to this, reinforced concrete was used but little in the United States. Ransome built his first important structure in 1890, the Leland Stanford, Jr., Museum Building, 312 ft. long, two stories high, with basement, the walls and floors of which were of reinforced concrete. Since 1891, when the first slabs of reinforced concrete were used in America, the development has been rapid.

The introduction of this form of construction proceeded more slowly in Europe, and between 1891 and 1894 Moeller in Germany, Wünsch and Emperger in Hungary, Melan in Austria, and Hennebique in France, were pioneers in its development. Hennebique built reinforced concrete slabs as early as 1879, but did not patent his system of construction until 1892.

The first published method of computation was by Koenen and Wayss in 1886. Subsequent theories have been advanced by de Mazas, Neuman, Melan, Coignet, de Tedesco, Von Thullie, Ostenfeld, Sanders, Spitzer, Lutken, Ritter, Hatt, Talbot, Turneaure, and others. As early as 1884, Ransome worked out methods of calculation independent of other investigators, and in 1899 Considère published his important series of tests from which he deduced his methods of calculation.

During the last ten years the earlier theories have been somewhat modified as experience has been gained and as the fund of experimental knowledge has accumulated. The trend of the modifications has been toward greater harmony in methods of calculation. Some of the earlier assumptions have been proved fallacious, and generally abandoned. On the other hand, some of the refinements of calculation, though known to be in accordance with facts, have, by general consent, been discarded, as they do not affect the design materially, or are taken into account by a modification of the constants. Among these are the value of the concrete in the tension side of a beam and the lack of a uniform modulus of elasticity in compression of concrete under widely varying stress. The earlier theories did not deal with the

diagonal tension under shearing stresses. This has been found to be a most important consideration, and much attention has been paid to it in recent years. In spite of the study which has already been given to it, however, there is still much to learn in this direction. The action of various forms of reinforcement in columns has received much consideration, and there is still a wide difference of opinion as to the efficacy of some forms of column reinforcement. Many experiments have been made in this branch of the subject, and practice appears to be gradually converging toward greater uniformity.

In the preparation of this historical sketch, the Committee has endeavored to verify the facts, and has received the co-operation of H. Kempton Dyson, Secretary of the Concrete Institute of England, Alfred Huser, President, Deutscher Beton-Verein, C. von Bach, Otto Leube, of Germany, Karl Naehr, of Austria, Joseph Schustler, of Hungary, and H. I. Hannover, of Denmark, to whom the Committee wishes to acknowledge its appreciation and thanks.

3.—Authorities on Which Recommendations are Based.

It has been suggested that a report such as this should include all the data on which conclusions are based. The impracticability of this may not be realized by those who are not familiar with the enormous quantity of matter involved. There are, however, reasons other than the magnitude of the task which tend to show that full publication is not advisable. One of these is that most of the experimental results have already appeared in print and are now available, and a reprint of them would be of no great advantage to any one. Where originally printed they are frequently accompanied with comments and deductions by their authors, which are of great value as such but could scarcely be copied by the Committee. Another reason against publication is that, in the large part of the experimental work consulted, it has been found that certain vitally important information, either with regard to the materials, the way in which they are manipulated, or as to the precise results reached, is lacking. The omission of measurements of deformations, of course, frequently renders results of little value. While such tests may have some use on account of particular facts developed, a large part may be useless, and consequently unsuitable for publication. The difficulty of separating the valuable from the valueless would be almost insurmountable.

It may not be improper, however, to append the following list of authors and references, as comprising a considerable part of the most important published material on the subject under consideration:

Regulations of Prussian Government, 1904, 1907.

Rules of French Government, 1907.

Recommendations of Swiss Society of Engineers and Architects, 1909.

Rules of the Austrian Ministry of the Interior, 1908, 1911.

In addition to the authorities above quoted, the Committee desires to acknowledge with thanks the discussions of its progress reports, which have appeared from time to time, and to say that all the points brought out therein have been carefully weighed.

4.—Character of Report Presented.

At the time of the appointment of the Committee, in 1904, there existed a great diversity of opinion in America as to methods of design, safe allowable working stresses, and methods of proportioning, hand-

ling, etc. A great deal of experimental work had been done, but there was need of a clearing house through which results could be compared and divergent views harmonized. During the interval between the appointment of the Committee and the preparation of its first Progress Report rapid advance was made in the art of concrete construction aided by the results of the investigations and the experience acquired by constructors. This report, which was submitted in 1909, attempted to embody recommendations for safe methods of construction and design in accordance with the best practice of the day. It would have been impossible for such a report to meet with the approval of all, and the Committee is well satisfied that its most vital recommendations have met with quite general acceptance by the engineers of the country.

Since the appearance of the first Progress Report, many experiments have been conducted by some of the technical institutions and by private and corporate interests, and through these and through longer experience in construction by its members and others, the Committee is now able to make some perfecting modifications of its former report and to add some entirely new material. The time, therefore, seems opportune for presenting this second report, bringing the work up to date.

The Committee would point out that while the report deals with every kind of stress to which concrete is subjected, and includes all ordinary conditions of proportioning and handling, it does not go into all types of construction or all the applications to which concrete and reinforced concrete may be put.

It is not to be assumed that the Committee in presenting this report wishes to imply that further improvements are not possible. A careful reading will disclose many points on which the present deductions are regarded as only tentative; but it has been the aim of the Committee to cover as fully as possible recommendations based on the present state of the art.

This report is what the word implies, and nothing more; it is not a "specification", but may be used as a basis for specifications.

The use of concrete and reinforced concrete involves the exercise of good judgment to a greater degree than for any other building material.

Rules cannot produce or supersede judgment; on the contrary, judgment should control the interpretation and application of rules.

II. Adaptability of Concrete and Reinforced Concrete.

The adaptability of concrete and reinforced concrete for engineering structures, or parts thereof, is now so well established that they may be considered the recognized materials of construction. They have proved satisfactory materials, when properly used, for those purposes for which their qualities make them particularly suitable.

1.—Uses.

Concrete is a material of very low tensile strength, and capable of sustaining but very small tensile deformations without rupture; its value as a structural material depends chiefly on its durability, its fire-resistive qualities, its strength in compression, its relatively low cost, and its adaptability to placing, especially where space is cramped or limited. Its strength increases generally with age.

Concrete is well adapted for structures in which the principal stresses are compressive, such as foundations, dams, retaining and other walls, tunnels, piers, abutments, short columns, and, in many cases, arches. In the design of massive concrete, the tensile strength of the material in resisting principal stresses must generally be neglected.

By the use of metal reinforcement to resist the principal tensile stresses, concrete becomes available for general use in a great variety of structures and structural forms. This combination of concrete and metal is particularly advantageous in the beam, where both compression and tension exist; it is also advantageous in the column, where the main stresses are compressive, but where cross-bending may exist. In structures resisting lateral forces, it possesses advantages over plain concrete in that it may be designed so as to utilize more fully the strength rather than the weight of the material. Metal reinforcement may also be of value in distributing cracks due to shrinkage and temperature changes.

2.—Precautions.

Failures of reinforced concrete structures are usually due to any one or a combination of the following causes: defective design, poor material, faulty execution, and premature removal of forms.

The defects in a design may be many and various. The computations and assumptions on which they were based may be faulty and contrary to the established principles of statics and mechanics; the unit stresses used may be excessive, or the details of the design defective.

Articulated concrete structures designed in imitation of steel trusses, may be mentioned as illustrating a questionable use of reinforced concrete, and such structures are not recommended.

Poor material is sometimes used for the concrete, as well as for the reinforcement. The use of poor aggregates, especially sand, which have not been tested, is a common source of defect. Inferior concrete is frequently due also to lack of experience on the part of the contractor and his superintendents, or to the absence of proper supervision.

An unsuitable quality of metal for reinforcement is sometimes prescribed in specifications, for the purpose of reducing the cost. For steel structures, a high grade of material is specified, but the steel used

for reinforcing concrete is sometimes made of unsuitable, brittle material.

Faulty execution, careless workmanship, and too early removal of forms may generally be attributed to unintelligent or insufficient supervision.

3.—Responsibility and Supervision.

The design of reinforced concrete structures should receive at least the same careful consideration as those of steel, and only engineers with sufficient experience and good judgment should be intrusted with such work.

The computations should include all minor details, which are sometimes of the utmost importance. The design should show clearly the size and position of the reinforcement, and should provide for proper connections between the component parts, so that they cannot be displaced. As the connections between reinforced concrete members are frequently a source of weakness, the design should include a detailed study of such connections, accompanied by computations to prove their strength.

While other engineering structures on the safety of which human lives depend are generally designed by engineers employed by the owner, and the contracts let on the engineer's design and specifications, in accordance with legitimate practice, reinforced concrete structures frequently are designed by contractors or by engineers commercially interested, and the contract let for a lump sum.

The construction of buildings in large cities is regulated by ordinances or building laws, and the work is inspected by municipal authorities. For reinforced concrete work, however, the limited supervision which municipal inspectors are able to give is not sufficient. Therefore, means for more adequate supervision and inspection should be provided.

The execution of the work should not be separated from the design, as intelligent supervision and successful execution can be expected only when both functions are combined. The engineer who prepares the design and specifications, therefore, should have the supervision of the execution of the work.

The Committee recommends the following rules for structures of reinforced concrete for the purpose of fixing the responsibility and providing for adequate supervision during construction:

(*a*) Before work is commenced, complete plans shall be prepared, accompanied by specifications, stress computations, and descriptions showing the general arrangement and all details. The plans shall show the size, length, dimensions for points of bending, and exact position of all reinforcement, including stirrups, ties, hooping, and splicing.

The computations shall give the loads assumed separately, such as dead and live loads, wind, and impact, if any, and the resulting stresses.

(*b*) The specifications shall state the qualities of the materials to be used for making the concrete, and the manner in which they are to be proportioned.

(*c*) The strength which the concrete is expected to attain after a definite period shall be stated in the specifications.

(*d*) The drawings and specifications shall be signed by the engineer and the contractor.

(*e*) Plans and specifications for all public structures should be approved by a legally authorized State or City official, and copies of such plans and specifications placed on file in his office.

(*f*) The approval of plans and specifications by other authorities shall not relieve the engineer or the contractor of responsibility.

(*g*) Inspection during construction shall be made by competent inspectors employed by and under the supervision of the engineer, and shall cover the following:

1. The materials.
2. The correct construction and erection of the forms and the supports.
3. The sizes, shapes, and arrangement of the reinforcement.
4. The proportioning, mixing, and placing of the concrete.
5. The strength of the concrete, by tests of standard test pieces made on the work.
6. Whether the concrete is sufficiently hardened before the forms and supports are removed.
7. Prevention of injury to any part of the structure by and after the removal of the forms.
8. Comparison of dimensions of all parts of the finished structure with the plans.

(*h*) Load tests on portions of the finished structure shall be made where there is reasonable suspicion that the work has not been properly performed, or that, through influences of some kind, the strength has been impaired. Loading shall be carried to such a point that one and three-quarters times the calculated working stresses in critical parts are reached, and such loads shall cause no injurious permanent deformations. Load tests shall not be made until after 60 days of hardening.

4.—Destructive Agencies.

(*a*) *Corrosion of Metal Reinforcement.*—Tests and experience indicate that steel sufficiently embedded in good concrete is well protected against corrosion, no matter whether located above or below water level. It is recommended that such protection be not less than 1 in. in thickness. If the concrete is porous, so as to be readily permeable

by water, as when the concrete is laid with a very dry consistency, the metal may corrode on account of the presence of moisture and air.

(*b*) *Electrolysis.*—The most recent experimental data available on this subject seem to show that while reinforced concrete structures may, under certain conditions, be injured by the flow of electric current in either direction between the reinforcing material and the concrete, such injury is generally to be expected only where voltages are considerably higher than those which usually occur in concrete structures in practice. If the iron be positive, trouble may manifest itself by corrosion of the iron accompanied by cracking of the concrete, and, if the iron be negative, there may be a softening of the concrete near the surface of the iron, resulting in a destruction of the bond. The former, or anode effect, decreases much more rapidly than the voltage, and almost if not quite disappears at voltages that are most likely to be encountered in practice. The cathode effect, on the other hand, takes place even on very low voltages, and is therefore more important from a practical standpoint than that of the anode.

Structures containing salt or calcium chloride, even in very small quantities, are very much more susceptible to the effects of electric currents than normal concrete, both the anode and cathode effects progressing much more rapidly in the presence of chlorine.

There is great weight of evidence to show that normal reinforced concrete structures free from salt are in very little danger under most practical conditions, while non-reinforced concrete structures are practically immune from electrolysis troubles.

The results of experiments now in progress may yield more conclusive information on this subject.

(*c*) *Sea Water.*—The data available concerning the effect of sea water on concrete or reinforced concrete are limited and inconclusive. Sea walls out of the range of frost action have been standing for many years without apparent injury. In many harbors where the water is brackish, through rivers discharging into them, serious disintegration has taken place. This has occurred chiefly between low and high tide levels, and is due, evidently, in part to frost. Chemical action also appears to be indicated by the softening of the mortar. To effect the best resistance to sea water, the concrete must be proportioned, mixed, and placed so as to prevent the penetration of sea water into the mass or through the joints. The cement should be of such chemical composition as will best resist the action of sea water; the aggregates should be carefully selected, graded, and proportioned with the cement so as to secure the maximum possible density; the concrete should be thoroughly mixed; the joints between old and new work should be made water-tight; and the concrete should be kept from exposure to sea water until it is thoroughly hard and impervious.

(*d*) *Acids.*—Concrete of first-class quality, thoroughly hardened, is affected appreciably only by strong acids which seriously injure other materials. A substance like manure is injurious to green concrete, but after the concrete has hardened thoroughly it resists the action of such acid satisfactorily.

(*e*) *Oils.*—When concrete is properly made and the surface is carefully finished and hardened, it resists the action of such mineral oils as petroleum and ordinary engine oils. Oils which contain fatty acids produce injurious effects, forming compounds with the lime which result in a disintegration of the concrete in contact with them.

(*f*) *Alkalies.*—The action of alkalies on concrete is problematical. In the reclamation of arid land, where the soil is heavily charged with alkaline salts, it has been found that concrete, stone, brick, iron, and other materials are injured under certain conditions. It would seem that at the level of the ground-water, in an extremely dry atmosphere, such structures are disintegrated, through the rapid crystallization of the alkaline salts, resulting from the alternate wetting and drying of the surface. Such destructive action can be prevented by the use of a protective coating, and is minimized by securing a dense concrete.

III. Materials.

A knowledge of the properties of the materials entering into concrete and reinforced concrete is the first essential. The importance of the quality of the materials used cannot be overestimated, and not only the cement but also the aggregates should be subject to such definite requirements and tests as will insure concrete of the desired quality.

1.—Cement.

There are available for construction purposes: Portland, Natural, and Puzzolan or Slag cements. Only Portland cement is suitable for reinforced concrete.

(*a*) *Portland Cement.*—This is the finely pulverized product resulting from the calcination to incipient fusion of an intimate mixture of properly proportioned argillaceous and calcareous materials. It has a definite chemical composition varying within comparatively narrow limits.

Portland cement should be used in reinforced concrete construction and any construction that will be subject to shocks or vibrations or stresses other than direct compression.

(*b*) *Natural Cement.*—This is the finely pulverized product resulting from the calcination of an argillaceous limestone at a temperature only sufficient to drive off the carbonic acid gas. Although the limestone must have a certain composition, this composition may vary within much wider limits than in the case of Portland cement. Natural cement does not develop its strength as quickly, nor is it as uniform in composition, as Portland cement.

Natural cement may be used in massive masonry where weight rather than strength is the essential feature.

Where economy is the governing factor, a comparison may be made between the use of natural cement and a leaner mixture of Portland cement that will develop the same strength.

(c) *Puzzolan or Slag Cement.*—This is the finely pulverized product resulting from grinding a mechanical mixture of granulated basic blast furnace slag and hydrated lime.

Puzzolan cement is not nearly as strong, uniform, or reliable as Portland or natural cement, is not used extensively, and never in important work; it should be used only for foundation work underground where it is not exposed to air or running water.

(d) *Specifications.*—The cement should meet the requirements of the Standard Methods of Testing and Specifications for Cement (see Appendix, p. 427), or as may be hereafter amended, the result of the joint labors of Special Committees of the American Society of Civil Engineers, American Society for Testing Materials, American Railway Engineering Association, and others.

2.—Aggregates.

Extreme care should be exercised in selecting the aggregates for mortar and concrete, and careful tests made of the materials for the purpose of determining their qualities and the grading necessary to secure maximum density* or a minimum percentage of voids.

(a) *Fine Aggregate.*—This should consist of sand, crushed stone, or gravel screenings, graded from fine to coarse, and passing when dry a screen having holes ¼ in. in diameter; it is preferable that it be of silicious material, and should be clean, coarse, free from dust, soft particles, vegetable loam, or other deleterious matter; and not more than 6% should pass a sieve having 100 meshes per lin. in. Fine aggregates should always be tested.

Fine aggregate should be of such quality that mortar composed of one part Portland cement and three parts fine aggregate by weight, when made into briquettes, will show a tensile strength at least equal to the strength of 1:3 mortar of the same consistency made with the same cement and standard Ottawa sand.† If the aggregate be of poorer quality, the proportion of cement in the mortar should be increased to secure the desired strength.

If the strength developed by the aggregate in the 1:3 mortar is less than 70% of the strength of the Ottawa sand mortar, the material should be rejected. To avoid the removal of any coating on the grains,

* A convenient coefficient of density is the ratio of the sum of the volumes of materials contained in a unit volume to the total unit volume.

† A natural sand obtained at Ottawa, Ill., passing a screen having 20 meshes and retained on a screen having 30 meshes per lin. in.; prepared and furnished by the Ottawa Silica Company, for 2 cents per lb., f. o. b. cars, Ottawa, Ill., under the direction of the Special Committee on Uniform Tests of Cement of the American Society of Civil Engineers.

which may affect the strength, bank sands should not be dried before being made into mortar, but should contain natural moisture. The percentage of moisture may be determined on a separate sample for correcting weight. From 10 to 40% more water may be required in mixing bank or artificial sands than for standard Ottawa sand to produce the same consistency.

(*b*) *Coarse Aggregate*.—This should consist of crushed stone or gravel which is retained on a screen having holes ¼ in. in diameter, and graded from the smallest to the largest particles; it should be clean, hard, durable, and free from all deleterious matter. Aggregates containing dust, and soft, flat, or elongated particles, should be excluded from important structures.

The maximum size of the coarse aggregate is governed by the character of the construction.

For reinforced concrete and for small masses of unreinforced concrete, the aggregate must be small enough to produce with the mortar a homogeneous concrete of viscous consistency which will pass readily between and easily surround the reinforcement and fill all parts of the forms.

For concrete in large masses, the size of the coarse aggregate may be increased, as a large aggregate produces a stronger concrete than a fine one, although it should be noted that the danger of separation from the mortar becomes greater as the size of the coarse aggregate increases.

Cinder concrete should not be used for reinforced concrete structures. It may be allowable in mass for very light loads or for fire protection purposes. The cinders used should be composed of hard, clean, vitreous clinker, free from sulphides, unburned coal, or ashes.

3.—Water.

The water used in mixing concrete should be free from oil, acid, alkalies, or organic matter.

4.—Metal Reinforcement.

The Committee recommends, as a suitable material for reinforcement, steel filling the requirements for structural steel reinforcement of the specifications adopted by the American Railway Engineering Association (Appendix, p. 430).

Where little bending or shaping is required, and also for reinforcement for shrinkage and temperature stresses, material filling the requirements of the specifications adopted by the American Railway Engineering Association for high-carbon steel (Appendix, p. 430) may be used, adopting the same unit stress as hereinafter recommended for structural grade material.

For the reinforcement of slabs, small beams, or minor details, or for reinforcement for shrinkage and temperature stresses, wire drawn from bars of the grade of rivet steel may be used, with the unit stresses hereinafter recommended.

The reinforcement should be free from excessive rust, scale, or coatings of any character which would tend to reduce or destroy the bond.

IV. Preparing and Placing Mortar and Concrete.

1.—Proportions.

The materials to be used in concrete should be carefully selected, of uniform quality, and proportioned with a view to securing as nearly as possible a maximum density.

(a) Unit of Measure.—The unit of measure should be the cubic foot. A bag of cement, containing 94 lb. net, should be considered the equivalent of 1 cu. ft.

The measurement of the fine and coarse aggregates should be by loose volume.

(b) Relation of Fine and Coarse Aggregates.—The fine and coarse aggregate should be used in such relative proportions as will insure maximum density. In unimportant work it is sufficient to do this by individual judgment, using correspondingly higher proportions of cement; for important work these proportions should be carefully determined by density experiments, and the sizing of the fine and coarse aggregates should be uniformly maintained or the proportions changed to meet the varying sizes.

(c) Relation of Cement and Aggregates.—For reinforced concrete construction, one part of cement to a total of six parts of fine and coarse aggregates measured separately should generally be used. For columns, richer mixtures are generally preferable, and in massive masonry or rubble concrete, a mixture of 1:9 or even 1:12 may be used.

These proportions should be determined by the strength or the wearing qualities required in the construction at the critical period of its use. Experienced judgment based on individual observation and tests of similar conditions in similar localities is an excellent guide as to the proper proportions for any particular case.

For all important construction, advance tests should be made of concrete, of the materials, proportions, and consistency to be used in the work. These tests should be made under laboratory conditions to obtain uniformity in mixing, proportioning, and storage, and in case the results do not conform to the requirements of the work, aggregates of a better quality should be chosen, or richer proportions used to obtain the desired results.

2.—Mixing.

The ingredients of concrete should be thoroughly mixed, and the mixing should continue until the cement is uniformly distributed and the mass is uniform in color and homogeneous. As the maximum density and greatest strength of a given mixture depend largely on thorough and complete mixing, it is essential that the work of mixing should receive special attention and care.

Inasmuch as it is difficult to determine, by visual inspection, whether the concrete is uniformly mixed, especially where limestone or aggregates having the color of cement are used, it is essential that the mixing should occupy a definite period of time. The minimum time will depend on whether the mixing is done by machine or hand.

(*a*) *Measuring Ingredients.*—Methods of measurement of the proportions of the various ingredients should be used which will secure separate and uniform measurements of cement, fine aggregate, coarse aggregate, and water, at all times.

(*b*) *Machine Mixing.*—When the conditions will permit, a machine mixer of a type which insures the uniform proportioning of the materials throughout the mass should be used, as a more uniform consistency can be thus obtained. The mixing should continue for a minimum time of at least 1 min. after all the ingredients are assembled in the mixer.

(*c*) *Hand Mixing.*—When it is necessary to mix by hand, the mixing should be on a water-tight platform, and especial precautions should be taken to turn all the ingredients together at least six times and until they are homogeneous in appearance and color.

(*d*) *Consistency.*—The materials should be mixed wet enough to produce a concrete of such a consistency as will flow into the forms and about the metal reinforcement when used, and which, at the same time, can be conveyed from the mixer to the forms without separation of the coarse aggregate from the mortar.

(*e*) *Retempering.*—Mortar or concrete should not be remixed with water after it has partly set.

3.—Placing Concrete.

(*a*) *Methods.*—Concrete, after the completion of the mixing, should be handled rapidly, and in as small masses as is practicable, from the place of mixing to the place of final deposit, and under no circumstances should concrete be used that has partly set. A slow-setting cement should be used when a long time is likely to occur between mixing and placing.

Concrete should be deposited in such a manner as will permit the most thorough compacting, such as can be obtained by working with a straight shovel or slicing tool kept moving up and down until all

the ingredients have settled in their proper places by gravity, and the surplus water has been forced to the surface. Special care should be exercised to prevent the formation of laitance, which hardens very slowly and forms a poor surface on which to deposit fresh concrete. All laitance should be removed.

Before depositing concrete, the reinforcement should be carefully placed in accordance with the plans, and adequate means provided to hold it in its proper position until the concrete has been deposited and compacted; care should be taken to see that the forms are substantial and thoroughly wetted (except in freezing weather) or oiled, and that the space to be occupied by the concrete is free from débris. When the placing of concrete is suspended, all necessary grooves for joining future work should be made before the concrete has had time to set.

When work is resumed, concrete previously placed should be roughened, thoroughly cleansed of foreign material and laitance, thoroughly wetted, and then slushed with a mortar consisting of one part Portland cement and not more than two parts fine aggregate.

The faces of concrete exposed to premature drying should be kept wet for a period of at least 7 days.

(*b*) *Freezing Weather.*—Concrete should not be mixed or deposited at a freezing temperature, unless special precautions are taken to avoid the use of materials covered with ice crystals or containing frost, and to provide means to prevent the concrete from freezing after being placed in position and until it has thoroughly hardened.

As the coarse aggregate forms the greater portion of the concrete, it is particularly important that this material be heated to well above the freezing point.

(*c*) *Rubble Concrete.*—Where the concrete is to be deposited in massive work, its value may be improved and its cost materially reduced by the use of clean stones thoroughly embedded in the concrete as near together as is possible and still entirely surrounded by concrete.

(*d*) *Under Water.*—In placing concrete under water, it is essential to maintain still water at the place of deposit. The use of tremies, properly designed and operated, is a satisfactory method of placing concrete through water. The concrete should be mixed very wet (more so than is ordinarily permissible) so that it will flow readily through the tremie and into the place with practically a level surface.

The coarse aggregate should be smaller than ordinarily used, and never more than 1 in. in diameter. The use of gravel facilitates mixing and assists the flow of concrete through the tremie. The mouth of the tremie should be buried in the concrete so far that it is at all times entirely sealed and the surrounding water prevented from forcing itself into the tremie; the concrete will then discharge without coming in contact with the water. The tremie should be suspended so that it can be lowered quickly when it is necessary either to choke off or prevent

too rapid flow; the lateral flow should preferably be not more than 15 ft.

The flow should be continuous, in order to produce a monolithic mass and prevent the formation of laitance in the interior.

In large structures it may be necessary to divide the mass of concrete into several small compartments or units, filling one at a time. With proper care, it is possible in this manner to obtain as good results under water as in the air.

V. Forms.

Forms should be substantial and unyielding, so that the concrete shall conform to the designed dimensions and contours; and they should be tight in order to prevent the leakage of mortar.

The time for removal of forms is one of the most important steps in the erection of a structure of concrete or reinforced concrete. Care should be taken to inspect the concrete and ascertain its hardness before removing the forms.

So many conditions affect the hardening of concrete that the proper time for the removal of the forms should be decided by some competent and responsible person, especially where the atmospheric conditions are unfavorable.

It may be stated in a general way that forms should remain in place longer for reinforced concrete than for plain or massive concrete, and that forms for floors, beams, and similar horizontal structures should remain in place much longer than for vertical walls.

When the concrete gives a distinctive ring under the blow of a hammer, it is generally an indication that it has hardened sufficiently to permit the removal of the forms with safety. If, however, the temperature is such that there is any possibility that the concrete is frozen, this test is not a safe reliance, as frozen concrete may appear to be very hard.

VI. Details of Construction.

1.—Joints.

(*a*) *Concrete.*—For concrete construction it is desirable to cast the entire structure at one operation, but as this is not always possible, especially in large structures, it is necessary to stop the work at some convenient point. This point should be selected so that the resulting joint may have the least possible effect on the strength of the structure. It is therefore recommended that the joints in columns be made flush with the lower side of the girders; that the joints in girders be at a point midway between supports, but should a beam intersect a girder at this point, the joint should be offset a distance equal to twice the width of the beam; that the joints in the members of a floor system should in general be made at or near the center of the span.

Joints in columns should be perpendicular to the axis of the column, and in girders, beams, and floor slabs perpendicular to the plane of their surfaces.

Girders should never be constructed over freshly formed columns without permitting a period of at least 2 hours to elapse, thus providing for settlement or shrinkage in the columns.

Shrinkage and contraction joints may be necessary in concrete subject to great fluctuations in temperature. The frequency of these joints will depend, first, on the range of temperature to which the concrete will be subjected, and second, on the quantity and position of the reinforcement. These joints should be determined, and provided for in the design. In massive work, such as retaining walls, abutments, etc., built without reinforcement, contraction joints should be provided at intervals of from 25 to 50 ft. and with reinforcement from 50 to 80 ft. (the smaller the height and thickness, the closer the spacing) throughout the length of the structure. To provide against the structure being thrown out of line by unequal settlement, each section of the wall should be tongued and grooved into the adjoining section. A groove should be formed in the surface of the concrete at vertical joints in walls or abutments.

Shrinkage and contraction joints should be lubricated by either an application of petroleum residuum oil or a similar material, so as to permit a free movement at the joint when the concrete expands or contracts.

The insertion of a sheet of copper or zinc, or even tarred paper, will be found advantageous in securing expansion and contraction at the joint.

(*b*) *Reinforcement.*—Wherever it is necessary to splice tension reinforcement, the length of lap should be determined on the basis of the safe bond stress, the stress in the bar, and the shearing resistance of the concrete at the point of splice; or a connection should be made between the bars of sufficient strength to carry the stress. Splices at points of maximum stress should be avoided. In columns, bars more than $\frac{3}{4}$ in. in diameter, not subject to tension, should be properly squared and butted in a suitable sleeve; smaller bars may be treated as indicated for tension reinforcement, or the stress may be cared for by embedment in large masses of concrete. At foundations, bearing plates should be provided for supporting the bars, or the bars may be carried into the footing a sufficient distance to transmit the stress of the steel to the concrete by means of the bearing and bond resistance; in no case shall the ends of the bars be permitted merely to rest on concrete.

2.—Shrinkage and Temperature Changes.

Shrinkage of concrete, due to hardening and contraction from temperature changes, causes cracks the size of which depends on the

extent of the mass. The resulting stresses are important in monolithic construction, and should be considered carefully by the designer; they cannot be counteracted successfully, but the effects can be minimized.

Large cracks, produced by quick hardening or wide ranges of temperature, can be broken up to some extent into small cracks by placing reinforcement in the concrete; in long continuous lengths of concrete, it is better to provide shrinkage joints at points in the structure where they will do little or no harm. Reinforcement is of assistance, and permits longer distances between shrinkage joints than when no reinforcement is used.

Small masses or thin bodies of concrete should not be joined to larger or thicker masses without providing for shrinkage at such points. Fillets similar to those used in metal castings, but of larger dimensions, for gradually reducing from the thicker to the thinner body, are of advantage.

Shrinkage cracks are likely to occur at points where fresh concrete is joined to that which is set, and hence, in placing the concrete, construction joints should be made on horizontal and vertical lines, and, if possible, at points where joints would naturally occur in dimension-stone masonry.

3.—Fire-Proofing.

The actual fire tests of concrete and reinforced concrete have been limited, but experience, together with the results of tests thus far made, indicates that concrete, on account of its low rate of heat conductivity and the fact that it is incombustible, may be used safely for fire-proofing purposes.

The dehydration of concrete probably begins at about 500° Fahr., and is completed at about 900° Fahr., but experience indicates that the volatilization of the water absorbs heat from the surrounding mass, which, together with the resistance of the air cells, tends to increase the heat resistance of the concrete, so that the process of dehydration is very much retarded. The concrete that is actually affected by fire remains in position and affords protection to the concrete beneath it.

The thickness of the protective coating required depends on the probable duration of a fire which is likely to occur in the structure, and should be based on the rate of heat conductivity. The question of the conductivity of concrete is one which requires further study and investigation before a definite rate for different classes of concrete can be fully established. However, for ordinary conditions, it is recommended that the metal in girders and columns be protected by a minimum of 2 in. of concrete; that the metal in beams be protected by a minimum of 1½ in. of concrete; and that the metal in floor slabs be protected by a minimum of 1 in. of concrete.

It is recommended that, in monolithic concrete columns, the concrete to a depth of $1\frac{1}{2}$ in. be considered as protective covering, and not included in the effective section.

It is recommended that the corners of columns, girders, and beams be beveled or rounded, as a sharp corner is more seriously affected by fire than a round one.

4.—Water-Proofing.

Many expedients have been used to render concrete impervious to water under normal conditions, and also under pressure conditions that exist in reservoirs, dams, and conduits of various kinds. Experience shows, however, that where mortar or concrete is proportioned to obtain the greatest practicable density and is mixed to a rather wet consistency, the resulting mortar or concrete is impervious under moderate pressure.

A concrete of dry consistency is more or less pervious to water, and compounds of various kinds have been mixed with the concrete, or applied as a wash to the surface for the purpose of making it water-tight. Many of these compounds are of but temporary value, and in time lose their power of imparting impermeability to the concrete.

In the case of subways, long retaining walls, and reservoirs, provided the concrete itself is impervious, cracks may be so reduced by horizontal and vertical reinforcement properly proportioned and located, that they are too minute to permit leakage, or are soon closed by infiltration of silt.

Coal-tar preparations, applied either as a mastic or as a coating on felt or cloth fabric, are used for water-proofing, and should be proof against injury by liquids or gases.

For retaining and similar walls in direct contact with the earth, the application of one or two coatings of hot coal-tar pitch to the thoroughly dried surface of concrete is an efficient method of preventing the penetration of moisture from the earth.

5.—Surface Finish.

Concrete is a material of an individual type, and should not be used in imitation of other structural materials. One of the important problems connected with its use is the character of the finish of exposed surfaces. The finish of the surface should be determined before the concrete is placed, and the work should be conducted so as to make possible the finish desired. For many forms of construction the natural surface of the concrete is unobjectionable, but frequently the marks of the boards and the flat dead surface are displeasing, making some special treatment desirable. A treatment of the surface, either by scrubbing it while green or by tooling it after it is hard, which removes the film of mortar and brings the aggregates of the concrete

into relief is frequently used to remove the form markings, break the monotonous appearance of the surface, and make it more pleasing. The plastering of surfaces, as ordinarily applied, should be avoided, for, even if carefully done, it is likely to peel off under the action of frost or temperature changes.

VII. Design.

1.—Massive Concrete.

In the design of massive or plain concrete, no account should be taken of the tensile strength of the material, and sections should usually be proportioned so as to avoid tensile stresses, except in slight amounts to resist indirect stresses. This will generally be accomplished, in the case of rectangular shapes, if the line of pressure is kept within the middle third of the section, but, in very large structures, such as high masonry dams, a more exact analysis may be required. Structures of massive concrete are able to resist unbalanced lateral forces by reason of their weight, hence the element of weight rather than strength often determines the design. A relatively cheap and weak concrete, therefore, will often be suitable for massive concrete structures.

It is desirable, generally, to provide joints at intervals, to localize the effect of contraction.

Massive concrete is suitable for dams, retaining walls, and piers and short columns in which the ratio of length to least width is relatively small. Under ordinary conditions, this ratio should not exceed six. It is also suitable for arches of moderate span, where the conditions as to foundations are favorable.

2.—Reinforced Concrete.

By the use of metal reinforcement to resist the principal tensile stresses, concrete becomes available for general use in a great variety of structures and structural forms. This combination of concrete and metal is particularly advantageous in the beam, where both compression and tension exist; it is also advantageous in the column, where the main stresses are compressive, but where cross-bending may exist. The theory of design, therefore, will relate mainly to the analysis of beams and columns.

3.—General Assumptions.

(*a*) *Loads.*—The loads or forces to be resisted consist of:

1. *The Dead Load.*—This includes the weight of the structure and fixed loads and forces.
2. *The Live Load.*—This consists of the loads and forces which are variable. The dynamic effect of the live load will often

require consideration. Any allowance for the dynamic effect is preferably taken into account by adding the desired amount to the live load or to the live-load stresses. The working stresses hereinafter recommended are intended to apply to the equivalent static stresses thus determined.

In the case of high buildings, the live load on columns may be reduced in accordance with the usual practice.

(*b*) *Lengths of Beams and Columns.*—The span length for beams and slabs shall be taken as the distance from center to center of supports, but need not be taken to exceed the clear span plus the depth of beam or slab. Brackets shall not be considered as reducing the clear span in the sense here intended.

The length of columns shall be taken as the maximum unsupported length.

(*c*) *Internal Stresses.*—As a basis for calculations relating to the strength of structures, the following assumptions are recommended:

1. Calculations will be made with reference to working stresses and safe loads, rather than with reference to ultimate strength and ultimate loads.
2. A plane section before bending remains plane after bending.
3. The modulus of elasticity of concrete in compression, within the usual limits of working stresses, is constant The distribution of compressive stresses in beams, therefore, is rectilinear.
4. In calculating the moment of resistance of beams, the tensile stresses in the concrete are neglected.
5. Perfect adhesion is assumed between concrete and reinforcement. Under compressive stresses, the two materials, therefore, are stressed in proportion to their moduli of elasticity.
6. The ratio of the modulus of elasticity of steel to the modulus of elasticity of concrete is taken at 15, except as modified in Chapter VIII, Section 8.
7. Initial stress in the reinforcement, due to contraction or expansion in the concrete, is neglected.

It is recognized that some of the assumptions given herein are not entirely borne out by experimental data. They are given in the interest of simplicity and uniformity, and variations from exact conditions are taken into account in the selection of formulas and working stresses.

The deflection of beams is affected by the tensile strength developed throughout the length of the beam. For calculations of deflections, a value of 8 for the ratio of the moduli will give results corresponding approximately with the actual conditions.

4.—T-Beams.

In beam and slab construction, an effective bond should be provided at the junction of the beam and slab. When the principal slab reinforcement is parallel to the beam, transverse reinforcement should be used, extending over the beam and well into the slab.

Where adequate bond and shearing resistance between slab and web of beam is provided, the slab may be considered as an integral part of the beam, but its effective width shall be determined by the following rules:

(*a*) It shall not exceed one-fourth of the span length of the beam;

(*b*) Its overhanging width on either side of the web, shall not exceed four times the thickness of the slab.

In the design of T-beams acting as continuous beams, due consideration should be given to the compressive stresses at the support. Beams in which the tee form is used only for the purpose of providing additional compression area of concrete should preferably have a width of flange not more than three times the width of the stem and a thickness of flange not less than one-third of the depth of the beam. Both in this form and in the beam and slab form, the web stresses and the limitations in placing and spacing the longitudinal reinforcement will probably be controlling factors in design.

5.—Floor Slabs.

Floor slabs should be designed and reinforced as continuous over the supports. If the length of the slab exceeds one and five-tenth times its width, the entire load should be carried by transverse reinforcement. Square slabs may well be reinforced in both directions.*

The continuous flat slab with multiple-way reinforcement is a type of construction used quite extensively, and has recognized ad-

* The exact distribution of load on square and rectangular slabs, supported on four sides and reinforced in both directions, cannot readily be determined. The following method of calculation is recognized as faulty, but it is offered as a tentative method which will give results on the safe side. The distribution of load is first to be determined by the formula:

$$r = \frac{l^4}{l^4 + b^4}$$

in which r = proportion of load carried by the transverse reinforcement, l = length, and b = breadth of slab. For various ratios of $\frac{l}{b}$ the values of r are as follows:

$\frac{l}{b}$	r
1	0.50
1.1	0.59
1.2	0.67
1.3	0.75
1.4	0.80
1.5	0.83

Using the values above specified, each set of reinforcement is to be calculated in the same manner as slabs having supports on two sides only, but the total amount of reinforcement thus determined may be reduced 25%, by gradually increasing the rod spacing from the third point to the edge of the slab.

vantages for special conditions, as in the case of warehouses with large, open, floor space. At present, a considerable difference of opinion exists among engineers as to the formulas and constants which should be used, but experience and tests are accumulating data which it is hoped will in the near future permit the formulation of the principles of design for this form of construction.

The loads carried to beams by slabs which are reinforced in two directions will not be uniformly distributed to the supporting beam, and its distribution will depend on the relative stiffness of the slab and the supporting beam. The distribution under ordinary conditions of construction may be expected to be that in which the load on the beam varies in accordance with the ordinates of a parabola having its vertex at the middle of the span. For any given design, the probable distribution should be ascertained, and the moments in the beam calculated accordingly.

6.—Continuous Beams and Slabs.

When the beam or slab is continuous over its supports, reinforcement should be fully provided at points of negative moment, and the stresses in concrete recommended in Chapter VIII, Section 4, should not be exceeded. In computing the positive and negative moments in beams and slabs continuous over several supports, due to uniformly distributed loads, the following rules are recommended:

(*a*) That for floor slabs, the bending moments at center and at support be taken at $\frac{wl^2}{12}$ for both dead and live loads, where w represents the load per linear foot and l the span length.

(*b*) That for beams, the bending moment at center and at support for interior spans be taken at $\frac{wl^2}{12}$, and for end spans it be taken at $\frac{wl^2}{10}$ for center and adjoining support, for both dead and live loads.

(*c*) In the case of beams and slabs continuous for two spans only, the bending moment at the central support should be taken as $\frac{wl^2}{8}$ and near the middle of the span as $\frac{wl^2}{10}$.

(*d*) At the ends of continuous beams, the amount of negative moment which will be developed will depend on the condition of restraint or fixedness, and this will depend on the form of construction used. There will usually be some restraint, and there is likely to be considerable. Provision should be made for the negative bending moment, but, as its amount will depend on the form of construction, the coefficient cannot be specified here, and must be left to the judgment of the designer.

For spans of unusual length, more exact calculations should be made. Special consideration is also required in the case of concentrated loads.

Even if the center of the span is designed for a greater bending moment than is called for by *a* or *b*, the negative moment at the support should not be taken as less than the values there given.

Where beams are reinforced on the compression side, the steel may be assumed to carry its proportion of stress, in accordance with the provisions of Chapter VII, Section 3, *c*-6. In the case of cantilever and continuous beams, tensile and compressive reinforcement over supports must extend sufficiently beyond the support and beyond the point of inflection to develop the requisite bond strength.

7.—Bond Strength, and Spacing of Reinforcement.

Adequate bond strength should be provided. The formula hereinafter given for bond stresses in beams is for straight longitudinal bars. In beams in which a portion of the reinforcement is bent up near the end, the bond stress at places in both the straight bars and the bent bars will be considerably greater than for all the bars straight, and the stress at some point may be several times as much as that found by considering the stress to be uniformly distributed along the bar. In restrained and cantilever beams, full tensile stress exists in the reinforcing bars at the point of support, and the bars must be anchored in the support sufficiently to develop this stress.

In case of anchorage of bars, an additional length of bar must be provided beyond that found on the assumption of uniform bond stress, for the reason that, before the bond resistance at the end of the bar can be developed, the bar may have begun to slip at another point, and "running" resistance is less than the resistance before slip begins.

Where high bond resistance is required, the deformed bar is a suitable means of supplying the necessary strength; but it should be recognized that, even with a deformed bar, initial slip occurs at early loads, and that the ultimate loads obtained in the usual tests for bond resistance may be misleading. Adequate bond strength throughout the length of a bar is preferable to end anchorage, but, as an additional safeguard, such anchorage may properly be used in special cases. Anchorage furnished by short bends at a right angle is less effective than hooks consisting of turns through 180 degrees.

The lateral spacing of parallel bars should not be less than three diameters, from center to center, nor should the distance from the side of the beam to the center of the nearest bar be less than two diameters. The clear spacing between two layers of bars should not be less than 1 in. The use of more than two layers is to be discouraged, unless the layers are tied together by adequate metal connections, particularly at and near points where bars are bent up or bent down.

8.—Diagonal Tension and Shear.

When a reinforced concrete beam is subjected to flexural action, diagonal tensile stresses are set up. If, in a beam not having web reinforcement, these stresses exceed the tensile strength of the concrete, failure of the beam will ensue. When web reinforcement, made up of stirrups, or of diagonal bars secured to the longitudinal reinforcement, or of longitudinal reinforcing bars bent up at several points, is used, new conditions prevail; but even in this case, at the beginning of loading, the diagonal tension developed is taken principally by the concrete, the deformations which are developed in the concrete permitting but little stress to be taken by the web reinforcement. When the resistance of the concrete to the diagonal tension is overcome at any point in the depth of the beam, greater stress is at once set up in the web reinforcement.

For homogeneous beams, the analytical treatment of diagonal tension is not very complex—the diagonal tensile stress is a function of the horizontal and vertical shearing stresses and of the horizontal tensile stress at the point considered, and as the intensity of these three stresses varies from the neutral axis to the remotest fiber, the intensity of the diagonal tension will be different at different points in the section, and will change with different proportionate dimensions of length to depth of beam. For the composite structure of reinforced concrete beams, an analysis of the web stresses, and particularly of the diagonal tensile stresses is very complex; and when the variations due to a change from no horizontal tensile stress in the concrete at the remotest fiber to the presence of horizontal tensile stress at some point below the neutral axis are considered, the problem becomes more complex and indefinite. Under these circumstances, in designing, recourse is had to the use of the calculated vertical shearing stress as a means of comparing or measuring the diagonal tensile stresses developed, it being understood that the vertical shearing stress is not the numerical equivalent of the diagonal tensile stress, and even that there is not a constant ratio between them. It is here recommended that the maximum vertical shearing stress in a section be used as the means of comparison of the resistance to diagonal tensile stress developed in the concrete in beams not having web reinforcement.

Even after the concrete has reached its limit of resistance to diagonal tension, if the beam has web reinforcement, conditions of beam action will continue to prevail, at least through the compression area, and the web reinforcement will be called on to resist only a part of the web stresses. From experiments with beams, it is concluded that it is safe practice to use only two-thirds of the external vertical shear in making calculations of the stresses that come on stirrups, diagonal web pieces, and bent-up bars, and it is here recommended for calculations in de-

signing that two-thirds of the external vertical shear be taken as producing stresses in web reinforcement.

Experiments bearing on the design of details of web reinforcement are not yet complete enough to allow more than general and tentative recommendations to be made. It is well established, however, that vertical members attached to or looped about horizontal members, inclined members secured to horizontal members in such a way as to insure against slip, and the bending of a part of the longitudinal reinforcement at an angle, will increase the strength of a beam against failure by diagonal tension, and that a well-designed and well-distributed web reinforcement may, under the best conditions, increase the total vertical shear carried to a value as much as three times that obtained when the bars are all horizontal and no web reinforcement is used. Where vertical stirrups are used without being secured to the longitudinal reinforcement, the force transmitted between longitudinal bar and stirrup must not be greater than can be taken through the concrete, and care must be taken to provide for the larger bond stress developed in the longitudinal bars with this construction than exists in the absence of stirrups. Sufficient bond resistance between the concrete and the stirrups or diagonals must be provided. Where the longitudinal bars are bent up, the points of bending of the several bars should be distributed along a portion of the length of the beam in such a way as to give efficient web reinforcement over the portion of the length of the beam in which it is needed. The higher resistance to diagonal tension failures given by unit frames having the stirrups and bent-up bars securely connected together both longitudinally and laterally is worthy of recognition. It is necessary that a limit be placed on the amount of shear which may be allowed in a beam; for when web reinforcement sufficiently efficient to give very high web resistance is used, at the higher stresses the concrete in the beam becomes checked and cracked in such a way as to endanger its durability as well as its strength.

The section to be taken as the critical section in the calculation of shearing stresses will generally be the one having the maximum vertical shear, though experiments show that the section at which diagonal tension failures occur is not just at a support, even though the shear at the latter point be much greater.

The longitudinal spacing of stirrups or diagonal members, or the distribution of the points of bending of adjacent bent-up bars, should not exceed three-fourths the depth of the beam.

It is important that adequate bond strength or anchorage be provided to develop fully the assumed strength of all web reinforcement.

It should be noted that it is on the tension side of a beam that diagonal tension develops in a critical way, and that the proper connection must always be made between stirrups or other web reinforcement and the

longitudinal tension reinforcement, whether the latter is on the lower side of the beam or on its upper side. Where negative moment exists, as is the case near the supports in a continuous beam, web reinforcement, to be effective, must be looped over, or wrapped around, or be connected with, the longitudinal tension reinforcing bars at the top of the beam, in the same way as is necessary at the bottom of the beam at sections where the bending moment is positive and the tension reinforcing bars are at the bottom of the beam.

Inasmuch as the smaller the longitudinal deformations in the horizontal reinforcement are, the less the tendency for the formation of diagonal cracks, a beam will be strengthened against diagonal tension failure by arranging and proportioning the horizontal reinforcement so that the unit stresses at points of large shear shall be relatively low.

Where pure shearing stress occurs, or shearing stress combined with but a small amount of tensile stress in the concrete, as when a concentrated load rests on a slab, or other forms of punching shear are produced, or in the case of compression pieces, the element of tension will not need consideration, and the permissible limit of the shearing stress will be higher than the allowable limit when this stress is used as a means of comparing diagonal tensile stress. The working values recommended are given in Chapter VIII, Working Stresses.

9.—Columns.

By columns are meant compression members of which the ratio of unsupported length to least width exceeds about six, and which are provided with reinforcement of one of the forms hereafter described.

It is recommended that the ratio of unsupported length of column to its least width be limited to 15.

The effective area of the column shall be taken as the area within the protective covering, as defined in Chapter VI, Section 3; or, in the case of hooped columns or columns reinforced with structural shapes, it shall be taken as the area within the hooping or structural shapes.

Columns may be reinforced by longitudinal bars, by bands, hoops, or spirals, together with longitudinal bars, or by structural forms which in themselves are sufficiently rigid to act as columns. The general effect of closely spaced hooping is greatly to increase the "toughness" of the column and its ultimate strength, but hooping has little effect on its behavior within the limit of elasticity. It thus renders the concrete a safer and more reliable material, and should permit the use of a somewhat higher working stress. The beneficial effects of "toughening" are adequately provided by a moderate amount of hooping, a larger amount serving mainly to increase the ultimate strength and the possible deformation before ultimate failure.

Composite columns of structural steel and concrete in which the steel forms a column by itself, should be designed with caution.

To classify this type as a concrete column reinforced with structural steel is hardly permissible, as the steel will generally take the greater part of the load. When this type of column is used, the concrete should not be relied on to tie the steel units together or to transmit stresses from one unit to another. The units should be adequately tied together by tie-plates or lattice bars, which, together with other details, such as splices, etc., should be designed in conformity with standard practice for structural steel. The concrete may exert a beneficial effect in restraining the steel from lateral deflection, and also in increasing the carrying capacity of the column. The proportion of load to be carried by the concrete will depend on the form of the column and the method of construction. Generally, for high percentages of steel, the concrete will develop relatively low unit stresses, and caution should be used in placing dependence on the concrete.

The following recommendations are made for the relative working stresses in the concrete for the several types of columns:

(*a*) Columns with longitudinal reinforcement only, to the extent of not less than 1% and not more than 4%: the unit stress recommended for axial compression in Chapter VIII, Section 3.

(*b*) Columns with reinforcement of bands, hoops, or spirals, as hereinafter specified: stresses 20% higher than given for *a*, provided the ratio of the unsupported length of the column to the diameter of the hooped core is not more than 8.

(*c*) Columns reinforced with not less than 1% and not more than 4% of longitudinal bars, and with bands, hoops, or spirals, as hereinafter specified: stresses 45% higher than given for *a*, provided the ratio of the unsupported length of the column to the diameter of the hooped core is not more than 8.

The foregoing recommendations are based on the following conditions:

In all cases, longitudinal reinforcement is assumed to carry its proportion of stress, in accordance with Section 3. The hoops or bands are not to be counted on directly as adding to the strength of the column.

Bars composing longitudinal reinforcement shall be straight, and shall have sufficient lateral support to be securely held in place until the concrete has set.

Where hooping is used, the total amount of such reinforcement shall be not less than 1% of the volume of the column enclosed. The clear spacing of such hooping shall be not greater than one-sixth of the

diameter of the enclosed column, and preferably not greater than one-tenth, and in no case more than 2½ in. Hooping is to be circular, and the ends of bands must be united in such a way as to develop their full strength. Adequate means must be provided to hold bands or hoops in place so as to form a column, the core of which shall be straight and well centered. The strength of hooped columns depends very much on the ratio of length to diameter of hooped core, and the strength due to hooping decreases rapidly as this ratio increases beyond five. The working stresses recommended are for hooped columns with a length of not more than eight diameters of the hooped core.

Bending stresses due to eccentric loads and lateral forces must be provided for by increasing the section until the maximum stress does not exceed the values above specified; and, where tension is possible in the longitudinal bars, adequate connection between the ends of the bars must be provided to take this tension.

10.—Reinforcing for Shrinkage and Temperature Stresses.

When areas of concrete too large to expand and contract freely as a whole are exposed to atmospheric conditions, the changes of form due to shrinkage (resulting from hardening) and to action of temperature are such that cracks may occur in the mass, unless precautions are taken to distribute the stresses so as to prevent the cracks altogether, or to render them very small. The distance apart of the cracks, and consequently their size, will be directly proportional to the diameter of the reinforcement and to the tensile strength of the concrete, and inversely proportional to the percentage of reinforcement and also to its bond resistance per unit of surface area. To be most effective, therefore, reinforcement (in amount generally not less than one-third of 1%) of a form which will develop a high bond resistance should be placed near the exposed surface and be well distributed. The allowable size and spacing of cracks depends on various considerations, such as the necessity for water-tightness, the importance of appearance of the surface, and the atmospheric changes.

VIII. Working Stresses.

1.—General Assumptions.

The following working stresses are recommended for static loads. Proper allowances for vibration and impact are to be added to live loads where necessary to produce an equivalent static load before applying the unit stresses in proportioning parts.

In selecting the permissible working stress to be allowed on concrete, we should be guided by the working stresses usually allowed for other materials of construction, so that all structures of the same class but composed of different materials may have approximately the same degree of safety.

The following recommendations as to allowable stresses are given in the form of percentages of the ultimate strength of the particular concrete which is to be used; this ultimate strength is to be that developed in cylinders 8 in. in diameter and 16 in. long of the consistency described in Chapter IV, Section 2 (*a*), made and stored under laboratory conditions, at an age of 28 days. In the absence of definite knowledge, in advance of construction, as to just what strength may be expected, the Committee submits the following values as those which should be obtained with materials and workmanship in accordance with the recommendations of this report.

Although occasional tests may show higher results than those here given, the Committee recommends that these values should be the maximum used in design.

TABLE OF STRENGTHS OF DIFFERENT MIXTURES OF CONCRETE.

(In Pounds per Square Inch.)

Aggregate.	1:1:2	1:1½:3	1:2:4	1:2½:5	1:3:6
Granite, trap rock	3 300	2 800	2 200	1 800	1 400
Gravel, hard limestone and hard sandstone.	3 000	2 500	2 000	1 600	1 300
Soft limestone and sandstone	2 200	1 800	1 500	1 200	1 000
Cinders.	800	700	600	500	400

NOTE.—For variations in the moduli of elasticity see Chapter VIII, Section 8.

2.—Bearing.

When compression is applied to a surface of concrete of at least twice the loaded area, a stress of 32.5% of the compressive strength may be allowed.

3.—Axial Compression.

For concentric compression on a plain concrete column or pier, the length of which does not exceed 12 diameters, 22.5% of the compressive strength may be allowed.

For other forms of columns the stresses obtained from the ratios given in Chapter VII, Section 9, may govern.

4.—Compression in Extreme Fiber.

The extreme fiber stress of a beam, calculated on the assumption of a constant modulus of elasticity for concrete under working stresses, may be allowed to reach 32.5% of the compressive strength. Adjacent to the support of continuous beams stresses 15% higher may be used.

5.—Shear and Diagonal Tension.

In calculations on beams in which the maximum shearing stress in a section is used as the means of measuring the resistance to diagonal tension stress, the following allowable values for the maximum vertical shearing stress are recommended:

(*a*) For beams with horizontal bars only and without web reinforcement calculated by the method given in the Appendix, Formula (22): 2% of the compressive strength.

(*b*) For beams thoroughly reinforced with web reinforcement: the value of the shearing stress calculated as for *a* (that is, using the total external vertical shear in Formula (22) for shearing unit stress), must not exceed 6% of the compressive strength. The web reinforcement, exclusive of bent-up bars, in this case, shall be proportioned to resist two-thirds of the external vertical shear in the formulas given in the Appendix, Formulas (24) or (25).

(*c*) For beams in which part of the longitudinal reinforcement is used in the form of bent-up bars distributed over a portion of the beam in a way covering the requirements for this type of web reinforcement: the limit of maximum vertical shearing stress (the stress calculated as for *a*), 3% of the compressive strength.

(*d*) Where punching shear occurs, that is, shearing stress uncombined with compression normal to the shearing surface, and with all tension normal to the shearing plane provided for by reinforcement: a shearing stress of 6% of the compressive strength may be allowed.

6.—Bond.

The bond stress between concrete and plain reinforcing bars may be assumed at 4% of the compressive strength, or 2% in the case of drawn wire.

7.—Reinforcement.

The tensile or compressive strength in steel should not exceed 16 000 lb. per sq. in.

In structural steel members, the working stresses adopted by the American Railway Engineering Association are recommended.

8.—Modulus of Elasticity.

The value of the modulus of elasticity of concrete has a wide range, depending on the materials used, the age, the range of stresses between which it is considered, as well as other conditions. It is recommended that in computations for the position of the neutral axis and for the resisting moment of beams and for the compression of concrete in columns it be assumed as:

(*a*) One-fifteenth of that of steel, when the strength of the concrete is taken as 2 200 lb. per. sq. in. or less.

(*b*) One-twelfth of that of steel, when the strength of the concrete is taken as greater than 2 200 lb. per sq. in., or less than 2 900 lb. per sq. in., and

(*c*) One-tenth of that of steel, when the strength of the concrete is taken as greater than 2 900 lb. per sq. in.

Although not rigorously accurate, these assumptions will give safe results. For the deflection of beams which are free to move longitudinally at the supports, in using formulas for deflection which do not take into account the tensile strength developed in the concrete, a modulus one-eighth of that of steel is recommended.

Respectfully submitted,

J. R. WORCESTER, *Chairman*,

R. W. LESLEY,
A. N. TALBOT,
EMIL SWENSSON.

DECEMBER, 1912.

IX. Appendix.

1.—Standard Specifications.

(a) *Cement.**

GENERAL OBSERVATIONS.

1.—These remarks have been prepared with a view of pointing out the pertinent features of the various requirements and the precautions to be observed in the interpretation of the results of the tests.

2.—The Committee would suggest that the acceptance or rejection under these specifications be based on tests made by an experienced person having the proper means for making the tests.

SPECIFIC GRAVITY.

3.—Specific gravity is useful in detecting adulteration. The results of tests of specific gravity are not necessarily conclusive as an indication of the quality of a cement, but when in combination with the results of other tests may afford valuable indications.

FINENESS.

4.—The sieves should be kept thoroughly dry.

TIME OF SETTING.

5.—Great care should be exercised to maintain the test pieces under as uniform conditions as possible. A sudden change or wide range of temperature in the room in which the tests are made, a very dry or humid atmosphere, and other irregularities, vitally affect the rate of setting.

CONSTANCY OF VOLUME.

6.—The tests for constancy of volume are divided into two classes, the first normal, the second accelerated. The latter should be regarded as a precautionary test only, and not infallible. So many conditions enter into the making and interpreting of it that it should be used with extreme care.

7.—In making the pats, the greatest care should be exercised to avoid initial strains due to moulding or to too rapid drying-out during the first 24 hours. The pats should be preserved under the most uniform conditions possible, and rapid changes of temperature should be avoided.

8.—The failure to meet the requirements of the accelerated tests need not be sufficient cause for rejection. The cement, however, may be held for 28 days, and a retest made at the end of that period, using a new sample. Failure to meet the requirements at this time should be considered sufficient cause for rejection, although in the present state of our

* Adopted August 16th, 1909, by the American Society for Testing Materials.

knowledge it cannot be said that such failure necessarily indicates unsoundness, nor can the cement be considered entirely satisfactory simply because it passes the tests.

General Conditions.

1. All cement shall be inspected.

2. Cement may be inspected either at the place of manufacture or on the work.

3. In order to allow ample time for inspecting and testing, the cement should be stored in a suitable weather-tight building having the floor properly blocked or raised from the ground.

4. The cement shall be stored in such a manner as to permit easy access for proper inspection and identification of each shipment.

5. Every facility shall be provided by the contractor, and a period of at least 12 days allowed for the inspection and necessary tests.

6. Cement shall be delivered in suitable packages, with the brand and name of manufacturer plainly marked thereon.

7. A bag of cement shall contain 94 lb. of cement net. Each barrel of Portland cement shall contain 4 bags, and each barrel of natural cement shall contain 3 bags of the above net weight.

8. Cement failing to meet the 7-day requirements may be held awaiting the results of the 28-day tests before rejection.

9. All tests shall be made in accordance with the methods proposed by the Special Committee on Uniform Tests of Cement of the American Society of Civil Engineers, presented to the Society on January 17th, 1912, with all subsequent amendments thereto.

10. The acceptance or rejection shall be based on the following requirements:

Natural Cement.

11. *Definition.*—This term shall be applied to the finely pulverized product resulting from the calcination of an argillaceous limestone at a temperature only sufficient to drive off the carbonic acid gas.

FINENESS.

12. It shall leave by weight a residue of not more than 10% on the No. 100, and 30% on the No. 200 sieve.

TIME OF SETTING.

13. It shall not develop initial set in less than 10 min., and shall not develop hard set in less than 30 min., or more than 3 hours.

TENSILE STRENGTH.

14. The minimum requirements for tensile strength for briquettes 1 sq. in. in cross-section shall be as follows, and the cement shall show no retrogression in strength within the periods specified:

Age.	*Neat Cement.*	Strength.
24 hours in moist air	....	75 lb.
7 days (1 day in moist air, 6 days in water)	....	150 "
28 days (1 day in moist air, 27 days in water)	....	250 "
	One Part Cement, Three Parts Standard Ottawa Sand.	
7 days (1 day in moist air, 6 days in water)	....	50 lb.
28 days (1 day in moist air, 27 days in water)	....	125 "

CONSTANCY OF VOLUME.

15. Pats of neat cement about 3 in. in diameter, ½ in. thick at the center, tapering to a thin edge, shall be kept in moist air for a period of 24 hours.

(*a*) A pat is then kept in air at normal temperature.

(*b*) Another is kept in water maintained as near 70° Fahr. as practicable.

16. These pats are observed at intervals for at least 28 days, and, to pass the tests satisfactorily, should remain firm and hard and show no signs of distortion, checking, cracking, or disintegrating.

PORTLAND CEMENT.

17. *Definition.*—This term is applied to the finely pulverized product resulting from the calcination to incipient fusion of an intimate mixture of properly proportioned argillaceous and calcareous materials, and to which no addition greater than 3% has been made subsequent to calcination.

SPECIFIC GRAVITY.

18. The specific gravity of cement shall be not less than 3.10. Should the test of cement as received fall below this requirement, a second test may be made on a sample ignited at a low red heat. The loss in weight of the ignited cement shall not exceed 4 per cent.

FINENESS.

19. It shall leave by weight a residue of not more than 8% on the No. 100, and not more than 25% on the No. 200 sieve.

TIME OF SETTING.

20. It shall not develop initial set in less than 30 min.; and must develop hard set in not less than 1 hour, nor more than 10 hours.

TENSILE STRENGTH.

21. The minimum requirements for tensile strength for briquettes 1 sq. in. in cross-section shall be as follows, and the cement shall show no retrogression in strength within the periods specified:

Age.	*Neat Cement.*	Strength.
24	hours in moist air	175 lb.
7	days (1 day in moist air, 6 days in water)	500 "
28	days (1 day in moist air, 27 days in water)	600 "

One Part Cement, Three Parts Standard Ottawa Sand.

7	days (1 day in moist air, 6 days in water)	200 lb.
28	days (1 day in moist air, 27 days in water)	275 "

CONSTANCY OF VOLUME.

22. Pats of neat cement about 3 in. in diameter, ½ in. thick at the center, and tapering to a thin edge, shall be kept in moist air for a period of 24 hours.

(*a*) A pat is then kept in air at normal temperature and observed at intervals for at least 28 days.

(*b*) Another pat is kept in water maintained as near 70° Fahr. as practicable, and observed at intervals for at least 28 days.

(*c*) A third pat is exposed in any convenient way in an atmosphere of steam, above boiling water, in a loosely closed vessel for 5 hours.

23. These pats, to pass the requirements satisfactorily, shall remain firm and hard, and show no signs of distortion, checking, cracking, or disintegrating.

SULPHURIC ACID AND MAGNESIA.

24. The cement shall not contain more than 1.75% of anhydrous sulphuric acid (SO_3), nor more than 4% of magnesia (MgO).

(*b*) *Metal Reinforcement.**

6.—Steel shall be made by the open-hearth process. Re-rolled material will not be accepted.

7.—Plates and shapes used for reinforcement shall be of structural steel only. Bars and wire may be of structural steel or high-carbon steel.

8.—The chemical and physical properties shall conform to the following limits:

Elements Considered.	Structural Steel.	High-Carbon Steel.
Phosphorus, maximum, Basic	0.04 per cent.	0.04 per cent.
Phosphorus, maximum, Acid	0.06 " "	0.06 " "
Sulphur, maximum	0.05 " "	0.05 " "
Ultimate tensile strength. Pounds, per square inch	Desired. 60 000	Desired. 88 000
Elong. min. percentage in 8 in., Fig. 1	1 500 000† / Ult. tensile strength.	1 000 000 / Ult. tensile strength.
Character of fracture	Silky	Silky or finely granular.
Cold bends without fracture	180° flat ‡	180° $d = 4t$ §

* Adopted March 16th, 1910, by the American Railway Engineering Association.
† See Paragraph 15. ‡ See Paragraphs 16 and 17. § "$d = 4t$" signifies "around a pin having a diameter four times the thickness of the specimen."

9.—The yield point for bars and wire, as indicated by the drop of the beam, shall be not less than 60% of the ultimate tensile strength.

10.—If the ultimate strength varies more than 4 000 lb. for structural steel or 6 000 lb. for high-carbon steel, a retest shall be made on the same gauge, which, to be acceptable, shall be within 5 000 lb. for structural steel, or 8 000 lb. for high-carbon steel, of the desired ultimate.

11.—Chemical determinations of the percentages of carbon, phosphorus, sulphur, and manganese shall be made by the manufacturer from a test ingot taken at the time of the pouring of each melt of steel, and a correct copy of such analysis shall be furnished to the engineer or his inspector. Check analyses shall be made from finished material, if called for, in which case an excess of 25% above the required limits will be allowed.

12.—*Plates, Shapes, and Bars.*—Specimens for tensile and bending tests for plates and shapes shall be made by cutting, from the finished product, coupons which shall have both faces rolled and both edges

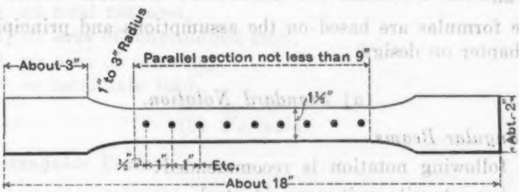

FIG. 1.—TENSION TEST PIECE.

milled to the form shown by Fig. 1; or with both edges parallel; or they may be turned to a diameter of ¾ in. with enlarged ends.

13.—Bars shall be tested in their finished form.

14.—At least one tensile and one bending test shall be made from each melt of steel as rolled. In case steel differing ⅜ in. and more in thickness is rolled from one melt, a test shall be made from the thickest and thinnest material rolled.

15.—For material less than $\frac{5}{16}$ in. and more than ¾ in. in thickness the following modifications will be allowed in the requirements for elongation:

(*a*) For each $\frac{1}{16}$ in. in thickness below $\frac{5}{16}$ in., a deduction of 2½ will be allowed from the specified percentage.

(*b*) For each ⅛ in. in thickness above ¾ in., a deduction of 1 will be allowed from the specified percentage.

16.—Bending tests may be made by pressure or by blows. Shapes and bars less than 1 in. thick shall bend as called for in Paragraph 8.

17.—Test specimens 1 in. thick and greater shall bend cold 180° around a pin, the diameter of which, for structural steel, is twice the

thickness of the specimen, and for high-carbon steel, is six times the thickness of the specimen, without fracture on the outside of the bend.

18.—Finished material shall be free from injurious seams, flaws, cracks, defective edges, or other defects, and have a smooth, uniform, and workmanlike finish.

19.—Every finished piece of steel shall have the melt number and the name of the manufacturer stamped or rolled on it, except that bar steel and other small parts may be bundled, with the above marks on an attached metal tag.

20.—Material which, subsequent to the above tests at the mills, and its acceptance there, develops weak spots, brittleness, cracks, or other imperfections, or is found to have injurious defects, will be rejected, and shall be replaced by the manufacturer at his own cost.

21.—All reinforcing steel shall be free from excessive rust, loose scale, or other coatings of any character which would reduce or destroy the bond.

2.—Suggested Formulas for Reinforced Concrete Construction.

These formulas are based on the assumptions and principles given in the chapter on design.

(a) *Standard Notation.*

1.—Rectangular Beams.

The following notation is recommended:

f_s = tensile unit stress in steel,
f_c = compressive unit stress in concrete,
E_s = modulus of elasticity of steel,
E_c = modulus of elasticity of concrete,
$n = \frac{E_s}{E_c}$,
M = moment of resistance, or bending moment in general,
A = steel area,
b = breadth of beam,
d = depth of beam to center of steel,
k = ratio of depth of neutral axis to effective depth d,
z = depth of resultant compression below top,
j = ratio of lever arm of resisting couple to depth d,
$jd = d - z$ = arm of resisting couple,
p = steel ratio (not percentage).

2.—T-Beams.

b = width of flange,
b' = width of stem,
t = thickness of flange.

3.—Beams Reinforced for Compression.

A' = area of compressive steel,
p' = steel ratio for compressive steel,
f_s' = compressive unit stress in steel,
C = total compressive stress in concrete,
C' = total compressive stress in steel,
d' = depth to center of compressive steel,
z = depth to resultant of C and C'.

4.—Shear and Bond.

V = total shear,
v = shearing unit stress,
u = bond stress per unit area of bar,
o = circumference or perimeter of bar,
Σ_0 = sum of the perimeters of all bars.

5.—Columns.

A = total net area,
A_s = area of longitudinal steel,
A_c = area of concrete,
P = total safe load.

(*b*) *Formulas.*

1.—Rectangular Beams.

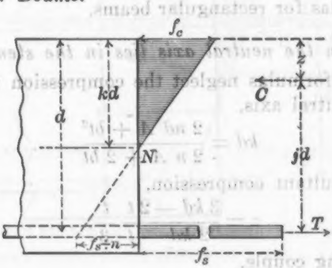

FIG. 2.

Position of neutral axis,

$$kd = \frac{2\,nd\,A + bt^2}{2\,n\,A + 2\,bt} \quad \text{.......(6)}$$

Position of resultant compression,

$$z = \frac{3\,kd - 2\,t}{2\,kd - t}\,\frac{t}{3} \quad \text{.......(7)}$$

Arm of resisting couple,

$$jd = d - z \quad \text{.......(8)}$$

Fiber stresses,

$$f_s = \frac{M}{Ajd} \quad \text{.......(9)}$$

$$f_c = \frac{Mkd}{bt\left(kd - \frac{1}{2}\,t\right)jd} = \frac{f_s}{n}\,\frac{k}{1-k} \quad \text{.......(10)}$$

(For approximate results, the formulas for rectangular beams may be used.)

The following formulas take into account the compression in the stem; they are recommended where the flange is small compared with the stem:

Position of neutral axis,

$$kd = \sqrt{\frac{2\,nd\,A + (b - b')\,t^2}{b'} + \left(\frac{nA + (b - b')\,t}{b'}\right)^2} - \frac{nA + (b - b')\,t}{b'} \quad \ldots\ldots (11)$$

Position of resultant compression,

$$z = \frac{\left(kdt^2 - \frac{2}{3}\,t^3\right) b + \left[(kd - t)^2 \left(t + \frac{1}{3}\,(kd - t)\right)\right] b'}{t\,(2\,kd - t)\,b + (kd - t)^2\,b'} \ldots (12)$$

Arm of resisting couple, $jd = d - z$ ....(13)

Fiber stresses,

$$f_s = \frac{M}{Ajd} \ldots\ldots (14)$$

$$f_c = \frac{2\,Mkd}{[(2\,kd - t)\,bt + (kd - t)^2\,b']\,jd} \ldots\ldots (15)$$

3.—Beams Reinforced for Compression.

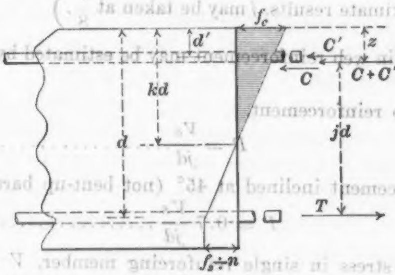

FIG. 4.

Position of neutral axis,

$$k = \sqrt{2\,n\left(p + p'\frac{d'}{d}\right) + n^2\,(p + p')^2} - n\,(p + p') \ldots (16)$$

Position of resultant compression,

$$z = \frac{\frac{1}{3}\,k^3\,d + 2\,p'\,nd'\left(k - \frac{d'}{d}\right)}{k^2 + 2\,p'\,n\left(k - \frac{d'}{d}\right)} \ldots\ldots (17)$$

Arm of resisting couple,

$$jd = d - z \qquad (18)$$

Fiber stresses,

$$f_c = \frac{6\,M}{bd^2\left[3\,k - k^2 + \frac{6\,p'\,n}{k}\left(k - \frac{d'}{d}\right)\left(1 - \frac{d'}{d}\right)\right]} \qquad (19)$$

$$f_s = \frac{M}{pjbd^2} = nf_c\,\frac{1-k}{k} \qquad (20)$$

$$f_s' = nf_c\,\frac{k - \frac{d'}{d}}{k} \qquad (21)$$

4.—Shear, Bond, and Web Reinforcement.

In the following formulas, Σ_0 refers only to the bars constituting the tension reinforcement at the section in question, and jd is the lever arm of the resisting couple at the section.

For rectangular beams,

$$v = \frac{V}{bjd} \qquad (22)$$

$$u = \frac{V}{jd\,\Sigma_0} \qquad (23)$$

(For approximate results, j may be taken at $\frac{7}{8}$.)

The stresses in web reinforcement may be estimated by the following formulas:

Vertical web reinforcement,

$$P = \frac{Vs}{jd} \qquad (24)$$

Web reinforcement inclined at 45° (not bent-up bars),

$$P = 0.7\,\frac{Vs}{jd} \qquad (25)$$

in which P = stress in single reinforcing member, V = amount of total shear assumed as carried by the reinforcement, and s = horizontal spacing of the reinforcing members.

The same formulas apply to beams reinforced for compression as regards shear and bond stress for tensile steel.

For T-beams,

$$v = \frac{V}{b'\,jd} \qquad (26)$$

$$u = \frac{V}{jd\,\Sigma_0} \qquad (27)$$

(For approximate results, j may be taken at $\frac{7}{8}$.)

5.—Columns.

Total safe load,

$$P = f_c (A_c + nA_s) = f_c A (1 + (n - 1) p) \quad \text{(28)}$$

Unit stresses,

$$f_c = \frac{P}{A (1 + (n - 1) p)} \quad \text{(29)}$$

$$f_s = n f_c \quad \text{(30)}$$

Paper No. 1290

THE EFFECT OF SATURATION ON THE STRENGTH OF CONCRETE.*

BY J. L. VAN ORNUM, M. AM. SOC. C. E.

WITH DISCUSSION BY MESSRS. E. A. MORITZ, J. R. WORCESTER, WALTER S. WHEELER, CLIFFORD RICHARDSON, W. K. HATT, HENRY H. QUIMBY, AND J. L. VAN ORNUM.

The paucity of recorded information concerning the treatment of concrete specimens, with regard to moisture conditions during their storage while awaiting the test for strength, seems to indicate a general supposition that this feature has no considerable effect on results. Apparently corroborating this attitude is the statement in the recent report of the Special Committee on Concrete and Reinforced Concrete, in which, while specifying the exact dimensions, mixing, consistency, age, etc., of test specimens, the only requirement designed to control moisture treatment during their curing seems to be that they shall be "stored under laboratory conditions." It is the purpose of this paper to invite attention, not only to the great importance of specifying and standardizing the moisture treatment of specimens intended for testing, but also to the further fact that similar conditions, as they act on the finished structures, will affect their strength considerably, and therefore should be considered in specifying the proper unit stresses. It is evident that this factor should not be ignored when great variations in strength, to an amount of perhaps 50% above or below a mean value, result from differences in moisture conditions.

* Presented at the meeting of November 5th, 1913.

During the last six years this question, at times, has been the subject of investigation in the Washington University Testing Laboratory. Different features have been explored experimentally, as work on graduation theses, since 1907 by Messrs. Trelease, Feinberg, Harris, Start, Bank, Caplan, Bryan, and Keller. Although these tests leave the greater part of the field still untouched, the writer believes the results thus far obtained to be so definite in their showing of a decided influence of moisture conditions on strength, and so significant in their general indications, that he offers this summarized statement of experimental results to the Engineering Profession for its consideration.

The most important part of the investigation is that of the effect, on the compressive strength of concrete, produced by varying systematically the relative length of time of exposure in air and in water.

The test specimens were cylindrical, 8 in. in diameter and 16 in. high. The materials were: a standard brand of Portland cement which fulfilled thoroughly all the requirements of the standard specifications; a clean sand of good quality, weighing about 100 lb. per cu. ft. when dry, and having 36% voids; and a washed river gravel of the same weight, varying in diameter from quite small up to 1½ in., and having 33% voids. The proportions were the usual 1:2:4, by volume; the mixing was done thoroughly by hand; and the quantity of water used was such as to give a moderately wet consistency, which allowed a thorough compacting by stirring with an iron rod and a slight tamping. All details of fabrication, curing, and testing were planned so as to secure such complete uniformity as is practicable to obtain in all regards except the one for which the controlled variation formed the particular purpose of the experimental study.

The cylinders were removed from the moulds when 2 days old, and were tested at an age of 6 weeks. The intervening 40 days constituted the period in which the duration of their immersion in water was varied systematically from nothing to the full time. The average results of the 240 tests thus made are plotted on the diagram, Fig. 1, on which the abscissas represent that number of days (after the 2 days in the moulds and the time of exposure to air) during which each set of specimens was placed in water before crushing them; and the ordinates give the percentage of strength which each set of immersed cylinders (standing in water for the indicated number of days) was found to have, taking the compressive strength of the dry specimens

from the same mix as 100 per cent. Thus, at the extreme left is represented the basis of comparison, or those which were not immersed at all; those specimens which were cured in air of ordinary humidity for 32 days and then immersed for 8 days are shown by the black circle to be 86% as strong as the air-cured concrete; those in air for 12 days

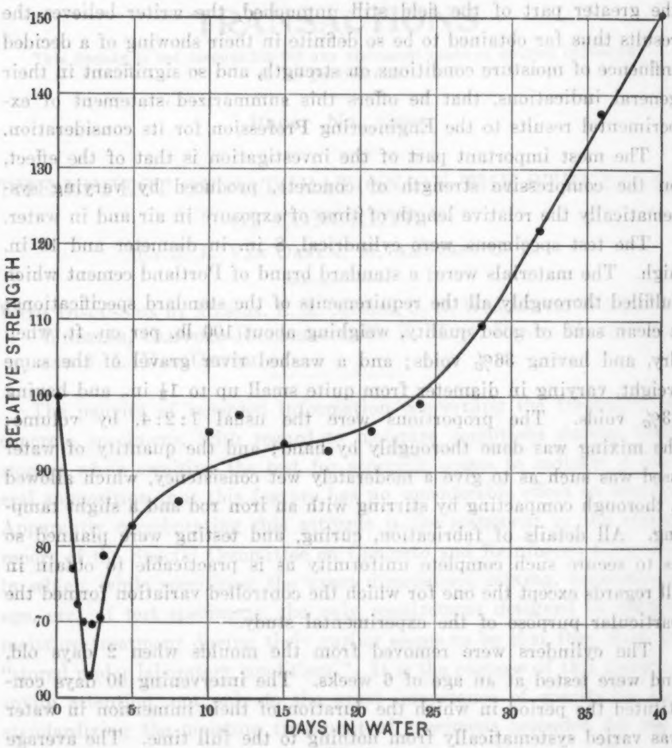

FIG. 1.

and therefore finally cured in water for 28 days have gained 9% in strength; and those submerged for the entire 40 days exhibited an average compressive strength fully 50% greater than that of the air-cured specimens.*

---

* Some other experiments have also shown that concrete aged entirely in water is considerably stronger than when left continuously in air, as reported by Rafter, Withey, and the Watertown Arsenal.

An average curve for the plotted points has been drawn as a full line, showing the systematic increase in strength as the time of submergence is lengthened beyond 2 days; but there exists the significant fact that specimens, of the dimensions used, decrease rapidly in strength when stored in air for 38 (or more) days and then placed in water for the remaining 2 days (or less). This particular feature of the rapid loss of strength on first exposure to water, and the active but slower recovery of strength as soaking continued, required a multiplication of tests to determine satisfactorily the locus of the curve in this region; and consequently more than half of the experiments were concentrated in this descending and the adjacent rising portion of the plot.

It thus appears that the compressive strength of concrete exposed only to air may be reduced nearly 40% when saturated with water, but that this loss is actively regained as the treatment is continued. The word saturation is used advisedly, because the minimum strength was found to coincide practically with the length of time required for water to penetrate to the middle of the specimens. Very plainly, this loss of strength has no relation to the percentage of contained moisture, as it is not only regained but much exceeded if the saturation is continued long enough. Perhaps the reduction in strength is purely a temporary physical phenomenon which is gradually counteracted and finally dominated by continued saturation permitting the imperfectly developed chemical processes of hardening to proceed actively. If this be true, concrete would regain something more than its original strength if dried out as soon as completely saturated, but this value would be less than that attainable by a continuance of the water treatment; also a repetition of soaking after such an experience would again temporarily reduce the strength, but less than before. These questions, as well as others, such as the duration of saturation necessary to prevent the temporary relapse of strength described, the corresponding effects of other periods of treatment similar to that discussed, of alternating the exposure to air and water, the result of different dimensions, proportions, materials, etc., all offer a large, interesting, and fruitful field for investigation.

In a series of experiments on the factors affecting the strength of bond between concrete and embedded steel, 74 tests were made to determine whether there existed the same tendency of rapid weakening at first and a following recovery of strength when the dry specimens

were immersed in water. The concrete was of the same character as already described, and the test specimens were partly of the notched beam type transversely loaded, and partly of cylindrical form in which the rod was pulled from the embedding concrete. All care was used to make the methods of testing such as to minimize all variables except the particular one the effect of which was sought. The results indicate clearly, for both plain and deformed bars, that the bond strength values, similarly, decline rapidly and then increase after saturation is complete, as is the case with the compressive strength; although the average minimum observed was only about 75% of that of the specimens cured entirely in air. Whether or not this percentage really marks the greatest weakening of bond produced by immersion at an age of 6 weeks is somewhat uncertain; perhaps additional tests for intermediate periods of soaking would have developed a further reduction in strength. At any rate, a similar behavior characterizes the bond values obtained during the first few days of saturation.

Thirty-two beams were made of such dimensions and amount of longitudinal reinforcement (without any web reinforcement whatever) that failure would always occur through the effect of the excessive web tension in the concrete. The materials were of the same quality as those already described, and equal precautions were taken to secure reliable results. These beams were also tested at an age of 6 weeks, but the small number restricted the investigation to lengths of immersion designed to detect only the early loss of web tensile strength and its subsequent increasing value, without tracing it throughout successively lengthening periods of exposure to water to the limit of 40 days. The characteristic effect is again the same, the lowest average found being again practically three-fourths of the strength of the air-cured specimens. It may be that, in this case also, the minimum value was not detected.

A series of experiments on concrete prisms when 7 years old, to determine any change due to age in elastic properties, has been discussed previously by the writer.* It may be stated, in reference thereto, that the modulus of elasticity of these old prisms exhibited a practically constant value throughout the repeated loadings equal to the maximum before found, which was about 80% greater than the final

* *Transactions*, Am. Soc. C. E., Vol. LVIII, pp. 312-13.

constant value as then reported for prisms of ordinary age; or a value of 4 000 000 in compression for that 1:3:5 limestone concrete. In these experiments two specimens were immersed in water until saturated and then carefully tested; the resulting compressive modulus of elasticity for wet concrete was 60% of that observed on the same specimens when dry. This lowering in value refers, again, only to the effect produced as soon as the saturation is complete; and has no reference to a continuance of the exposure to water, such as is reported on certain other tests,* where the figures given for the compressive modulus of elasticity of concrete specimens cured entirely in water for 26 days are about one-fourth greater than for those cured only in air.

As the various strength values of dry concrete are temporarily reduced from 25 to 40% by saturation, it would seem that this fact should be given definite consideration in fixing the working stresses used in the design of structures which may be thus exposed, or else conditions should be controlled in such a way as to prevent the weakening thus produced. No such effect occurs in concrete constantly under water or in moist earth from the time of its fabrication; but construction above ground, and therefore exposed to dry air for a time and then to a heavy rain or other source of rapid wetting, presents conditions under which this reduction in strength exists temporarily. Fortunately, the remedy is simple and inexpensive. It is to keep the exposed material thoroughly wet until its enclosure by exterior walls and roof renders its saturation by rain impossible. The case of parts not thus protected, or those for which enclosure is delayed, is not so simple; because the length of time of saturation which will make the concrete safe against serious reduction of strength is uncertain. The systematic wetting of concrete is a well-known principle of good construction; but the writer's observation and experience suggest a very considerable tendency to regard that procedure as abstractly correct, but practically rather specious or trivial. One purpose of this paper is to present the facts in such a way that the frequent, thorough, and faithful wetting of all parts of such concrete structures shall henceforth be no more ignored than is now the protection from freezing or disturbance while setting. Probably this treatment should be continued

* *Bulletin No. 175*, University of Wisconsin, p. 17.

for a length of time substantially greater than that heretofore indicated—perhaps for a period expressed in weeks instead of days.

Undoubtedly, carelessness in a thorough control of this kind is a frequent contributing cause of weakness which is sometimes sufficient to result in failure. Very evidently, this temporary weakening of concrete by saturation is amply covered by the factor of safety required by good practice, if it be the only fault; but the materials may be considerably below standard, or the workmanship may be defective, or the design may encroach on the reserve of safety, or the occasional overload may be imposed; and if the material man, the construction superintendent, the designer, and the user of the structure should each rely on the others to meet fully the requirements, in the expectation that his own delinquency will be safely covered by the factor of safety, it would not require an impossible coincidence of such conditions to cause disaster, especially in view of the fact that considerable variations from the average strength values, which form the basis of design, necessarily exist in different parts of the structure. In fact, the failures which have occurred are generally a result of several such contributing causes. The writer believes that the considerable weakening produced by the saturation of dry concrete has invariably been a contributing factor in all those instances in which there was an active wetting of dry or partly dry concrete when subjected to essential stresses.

This general proposition furnishes one more evidence of the remarkable responsiveness of concrete to variations in its treatment. The fact that differences in control (which to the average artisan are seemingly unimportant) actually do exert a positive influence on its essential characteristics, constitutes a definite warning against entrusting it to the uncertainties of irresponsible or skeptical supervision, and assures ample reward for a competent control which is correctly adapted to develop its capabilities. The susceptibility of steel to the influence of phosphorus and sulphur, of details of its heat treatment, and of other conditions occurring in the process of its manufacture, have resulted in restricting its production to the scrutiny of expert superintendence. Equal reason exists for, and commensurate advantages will follow, a thoroughly discriminating control of both the initial fabrication of concrete, and the details of treatment during its hardening, in order to realize the great possibilities inherent in this newer material.

The treatment of steel is not always complete as it comes from the rolls, as is shown by such effects as the changes in strength produced by the cold-twisting of steel rods; much more important in relation to the resulting quality of concrete is the nature of its treatment after fabrication, both because its attainment of strength is a relatively slow process and for the reason that the nature of the prevailing conditions provided during this period affects so greatly the development of its essential properties.

The notable responsiveness of concrete to the character of its treatment is a direct appeal for thoroughly trustworthy and expert control.

DISCUSSION

Mr. Moritz.

E. A. Moritz, Assoc. M. Am. Soc. C. E. (by letter).—This paper recalls some experiments conducted by the writer in 1904 and 1905 at the University of Wisconsin and published in 1906.* It was believed by the writer at that time that concrete stored in water before testing is much stronger than when stored in air for the same period of time, and he was much surprised then, and has been more surprised since, that this point has not been generally recognized in specifications for test pieces.

The writer's experiments were very limited, and were only incidental to some tests of large beams, but the results show up so forcibly the difference in strength of concrete specimens stored in water and those stored in air that it is thought worth while to publish them again in connection with Mr. Van Ornum's paper. The figures in Table 1 are taken from page 364 of the *Bulletin* mentioned. The figures in the last column are the reciprocals of those in the *Bulletin*, and are given in order to make them directly comparable with Mr. Van Ornum's figures.

All compression tests were made with 4-in. cubes, and at the age of 30 days. The cubes were taken from the moulds at the age of 48 hours, after which one from each batch was stored in air at a temperature of about 65°, and the other stored in water until tested. The concrete was mixed moderately wet—not sloppy. All materials were proportioned by weight and mixed by hand. Natural pit sand and crushed limestone formed the aggregate.

* *Bulletin No. 148*, University of Wisconsin.

J. R. WORCESTER, M. AM. SOC. C. E. (by letter).—The author has brought out in a forceful manner the possible loss of strength in concrete by saturation after premature drying, and, at the same time, the possible gain in strength by continuous saturation up to an age of 6 weeks. This series of tests furnishes ample evidence of the necessity of standardizing the method of curing specimens for compression tests in the laboratory, and may account for an appreciable part of the discrepancies often noticed between the results of experiments made in different laboratories. It also shows that by yielding to the temptation to allow concrete in actual construction to dry out as rapidly as possible, one runs the risk of permanently losing a very material proportion of the strength which might be attained, even though, by its location within a building, there is no danger of the loss of strength through subsequent saturation. Builders are very apt to strip forms from vertical surfaces as quickly as possible, to hasten this drying out, and engineers are likely to overlook the ill effect of this practice. Mr. Worcester.

It seems evident that the treatment to which the test specimens were subjected was calculated to produce unusually rapid drying out, and that the strength of those tested without subsequent immersion, taken as 100 on the scale of relative strengths, must have been rather lower than would naturally be expected of this quality of concrete. If so, the later gain in strength after continuous saturation is easily explained. The author, perhaps, will give us additional light on this point.

The temporary loss of strength on immersion appears to the writer to be analogous to the loss in strength of dried clay when water-soaked. It seems as if some of the cement was dried out so rapidly that it acquired a strength from drying and not from chemical crystallization. The formation of a hardened, light colored skin on the outside of a wall while the interior is still dark, moist, and soft, is a common phenomenon. If this is not the true explanation, the writer hopes that the discussion will bring out a better one.

Although the report of the Special Committee on Concrete and Reinforced Concrete does not elaborate the dangers of too rapid drying, as it might have done to advantage, it does include one recommendation, apparently overlooked by the author, that "The faces of concrete exposed to premature drying should be kept wet for a period of at least 7 days." It would be interesting to know what would have been the effect on the author's experiments of this initial treatment.

In actual construction it seems probable that generally a better chance for hydration exists than was given to these specimens. A cylinder, 8 in. in diameter and 16 in. high, removed from the mould in 2 days and exposed to air of ordinary humidity, would present a

Mr. Worcester. large surface to the effect of evaporation, and would dry out very rapidly. The exposed surface, assuming the cylinders to have stood on end, would have amounted to about 6.75 sq. ft. for each cubic foot of volume. In practice, prior to the removal of the forms, a floor slab would offer the largest exposed surface per unit of volume of any ordinary construction. In this case, with a thickness of 6 in., the exposed area would only be 2 sq. ft. for every cubic foot of volume, and, if the surface were kept wet for 7 days, as it should be, the chance for drying out would be much less than in the test cylinders. It appears, therefore, that though the danger of a decrease in strength from saturation is unlikely to prove serious in practice, it cannot justifiably be ignored.

Mr. Wheeler. WALTER S. WHEELER, M. AM. SOC. C. E. (by letter).—The writer has often noticed that in finished structures new concrete appears to lose part of its strength when first submerged in water. For example, he has just completed some construction in which the proportion was 1 part cement to 3 parts sand, by volume. When 2 or 3 days old, the top of this structure was submerged to a depth of about 1 ft. Before submersion, it was noted that, by pressing with the thumb on the corners and edges of the structure, the concrete could be broken quite easily, and that for several days after submersion it could be broken more easily; in fact, for a few days, it seemed that the structure had only about enough strength to hold together.

After a submersion of 2 months, the structure was as firm as could be expected, and nothing but a charge of dynamite could mar it. The materials used were standard, and the placing was done according to standard practice.

Mr. Richardson. CLIFFORD RICHARDSON, M. AM. SOC. C. E. (by letter).—The conclusions arrived at by Mr. Van Ornum can be confirmed by the experience of the writer, who, however, would go farther and state that a reversal of the conditions with which he has experimented would result in the diminution of the strength of the concrete; that is to say, that a concrete which has been immersed in water for some time loses strength on being dried out. It is to be hoped that Mr. Van Ornum, through some of his students, will conduct some experiments in this as well as in other directions where modification of the environment of concrete may take place. Mr. Van Ornum's paper is valuable, as it brings to the attention of users of concrete a situation which has not been sufficiently appreciated in the past, although it has been known, in a general way, to most engineers.

Mr. Hatt. W. K. HATT, M. AM. SOC. C. E. (by letter).—The writer is interested in and appreciates Professor Van Ornum's experimental inquiry. An intelligent use of materials must be promoted by a knowledge of their underlying properties and essential nature. This knowledge is

more likely to be gained by investigations of the character described in this paper than by elaborate and extensive empirical tests, mechanically planned and performed, which add to the work of the compiler and to the accumulation of débris that is carried along in textbooks and handbooks from one generation to another. Mr. Hatt.

The writer believes that, in this and also in a former paper,* Professor Van Ornum has failed to do justice to his tests, in that he has chosen not to accept the standards imposed by most experimenters upon themselves with respect to completeness of publication of the data. Every one knows that different persons may derive conflicting conclusions from the same data when the full circumstances are known. In the case of this paper, we must accept or reject deductions in respect to an important fundamental matter on the basis of a single diagram. The writer does not desire to be understood as saying that the diagram, with its experimental points and curve, is not the only expression of a law to be obtained from the data which are not published, but he expresses the wish that he, with others, might review the experimental facts independently. Much could also be learned from a report of the measurements of deformations and sets. Only a partial view is obtained from the compressive strength alone.

* Two months.

In 1906-07 the writer conducted an investigation on the effect of the time element in loading reinforced concrete beams.† Table 2, from that source, shows a constantly increasing deflection under con-

* "The Fatigue of Concrete," *Transactions*, Am. Soc. C. E., Vol. LVIII, p. 294.

† "Notes on the Effect of Time Element in Loading Reinforced Concrete Beams," *Transactions*, Am. Soc. for Testing Materials, Vol. VII, 1907.

Mr. Hatt. tinued load applied to such beams, and also that a repeated application of load produces permanent deflection and set without affecting the subsequent maximum load carried by the beam. In the writer's view, these facts expressed a plasticity in concrete.

In these cases the results could hardly be explained by the effect of water in softening the concrete, as reported by Professor Van Ornum. The beams were exposed outdoors, were protected from rain by a platform, and were tested under repetitive loads in the laboratory.

In arriving at a final view, some help is obtained from the behavior of other materials. The writer has noted an analogy between the behavior of concrete and wood with respect to the effects of certain conditions of loading.

In case of any material, one should know the effect of the following elements on the strength and deformation, both elastic and plastic:

(1). Time-rate of application of stress, including impact loading and long-continued steady loads;

(2). Moisture conditions;

(3). Temperature of material under (1).

(1). Wood exhibits an increasing deformation and set under loads which are continued over periods of days and weeks, and the final load is not affected by precedent sets. Mr. H. D. Tiemann has investigated this matter exhaustively.* Portland cement concrete also possesses this property.

As the speed of application of the load is increased, wood exhibits a higher elastic limit, which, under impact, may be double the static elastic limit. It is evidently affected by the time-rate of the application of loading. No data are known to the writer to determine the effect of speed of loading on concrete.

The final strength of both wood and concrete appears to be unaffected by precedent plastic changes which produce set.

(2). Wood also becomes more plastic when the wood substance contains more water. It is strong and stiff when dry, and weak and flexible when wet. Omitting the difference of the chemical action proceeding in concrete when in water, it appears from Professor Van Ornum's paper that concrete becomes weak when saturated with water. His deformation measurements, not reported, might show whether or not the modulus of elasticity was correspondingly decreased.

After wood is dried out and the excess moisture is removed, it nearly resumes its original properties. Professor Van Ornum suggests that concrete would regain something more than its original strength if dried out after being completely saturated.

* A report of part of his investigations will be found in *Transactions*, Am. Soc. for Testing Materials, Vol. IX (1909), p. 534, "Some Results of Dead Load Bending Tests of Timber by Means of a Recording Deflectometer"; and Vol. VIII (1908), p. 541, "The Effect of the Speed of Testing upon the Strength of Wood and the Standardization of Tests for Speed."

(3). No data are known to the writer to show conclusively the effect of temperature on the strength and deformation of either wood or concrete. Mr. Hatt.

The foregoing discussion indicates that the binding substance in wood and concrete exhibits marked plasticity, not alone under long-continued loadings at low stress, and that this substance is temporarily affected by the absorption of water.

Leaving the field of the writer's knowledge, he would take the liberty of referring to the views of others who consider the hardening of concrete as a phenomenon of colloidal action, and to the statement of those wise in the knowledge of wood substance that a colloidal material binds wood structure together. If this is so, we might expect, from the properties of colloids, that concrete and wood would show the noticed plasticity under long-continued loadings, the noticed effect of moisture on the strength; both should show a difference of behavior under quickly applied loads; and their strength should also be affected by temperature—being more brittle at low temperatures. The writer may be pardoned for sketching in this uncertain field.

Do not the author's results bear out the common view of workers in concrete that some part of the hardening of the concrete floor of a building under construction when exposed to the drying conditions of the atmosphere is due to this "drying out", irrespective of temperature? The writer has noticed the rapid gain in strength of concrete specimens shipped to the laboratory in tin forms after the latter had been removed. Specimens of concrete taken from building failures also gain strength rapidly when exposed to the air of the laboratory. This is no doubt due to hastened chemical action consequent on the increased temperature, but it also may be the process of drying out analogous to that prevailing in wooden beams. Professor Van Ornum coincides in this common view in his statement:

"In fact, the failures which have occurred are generally a result of several such contributing causes. The writer believes that the considerable weakening produced by the saturation of dry concrete has invariably been a contributing factor in all those instances in which there was an active wetting of dry or partly dry concrete when subjected to essential stresses."

Henry H. Quimby, M. Am. Soc. C. E.—Mr. Worcester's discussion brings up recollections of some early experience with concrete. Certain 6-in. test cubes made by an inspector in the field yielded very unsatisfactory results when crushed, breaking as low as 500 lb. per sq. in. The cement, which was a standard Portland brand, and the sand, which was New Jersey bank sand, were suspected and retested, but were found to be normal. The concrete was friable—the edges easily rubbed off with the thumb—and it was very absorbent. Tensile test briquettes of the mortar—1 to 3—made at the same time as the cubes, tested as Mr. Quimby.

Mr. Quimby. low as 39 lb. at 7 days. Some broken pieces partly immersed in water to observe their absorption were noticed after a few days to have considerably higher tenacity. Similar experiences on other work later, and also some experiments, made it clear that premature setting and drying out prevents concrete from properly ripening.

The trouble appears in hot weather, when all the materials have been heated by exposure to the sun, and perhaps when, in addition, a quick-setting cement is used. When concrete is found to be deficient in strength because of premature drying out, continued saturation with water will increase its strength, but will probably not raise it to the normal point unless the saturation be continued for a very long time.

It is evident that concrete wants its moisture and time together.

In order to secure uniform conditions of treatment of test cubes, the rule has been adopted for all inspectors to bury each cube in moist earth as soon as it is removed from the mould, and keep it there until it is sent in to the testing laboratory to be crushed.

Mr. Van Ornum. J. L. Van Ornum, M. Am. Soc. C. E. (by letter).—It is gratifying to note the several instances cited as showing the marked change in strength which results from saturating concrete which has been previously exposed in air. Undoubtedly there are many others, that have not been reported, which would indicate the same general tendency. Of course, the proportionate loss of strength occurring when an air-cured concrete is saturated would depend on a multiplicity of existing conditions, some of which have been referred to. One of these is the relatively large area of surface compared to volume in the test specimens, as noted by Mr. Worcester. It would seem probable, however, that the difference in loss of strength between the concrete in structures and that of the experiments would not be nearly as great as suggested by those comparative differences, because there is the partly compensating fact that structural members are generally exposed during construction to the drying effect of breezes and often to direct sunlight and a dry air, while the specimens were in a small closed room in which the air was comparatively moist. If, on the contrary, "the surface were kept wet for 7 days," it is believed that a large part of the loss on saturation would be avoided.

With regard to the values of deformations and sets, which Professor Hatt assumes were withheld, it can only be stated that circumstances prevented their determination in connection with the tests reported. The only additional information pertinent to the subject, which can be added, has reference to the suggestion of Mr. Worcester, that the actual strength of the specimens cured entirely in air "must have been rather lower than would naturally be expected of this quality of concrete." These cylindrical prisms averaged 1 760 lb. per sq. in. Though this is about one-tenth less than the compressive strength that may be fairly expected of good laboratory specimens of these materials

and proportions, they were actually somewhat stronger than the average of a large number of test prisms of similar concrete used in building construction and supposedly treated during curing in a way corresponding to that given to the material in the structures. Mr. Van Ornum.

The writer hesitated to publish the paper at all, because of the many supplementary questions remaining for investigation, the determination of which is necessary for a complete understanding of the phenomena involved. Nevertheless, he concluded that the field of further research would be made more definite and available to others if he presented the preliminary results already given. Of course, other percentage values will result from different experimental details, and the curve itself may be varied considerably in the same way. Yet it is believed that the broad, general fact of a significant loss in the strength of dry concrete when suddenly saturated and its gradual increase in strength to a final value considerably greater than the original one, when the saturation is prolonged, is a reality which should be definitely recognized in dealing with this important engineering material.

Paper No. 1291

COAL PIERS ON THE ATLANTIC SEABOARD.*

By J. E. Greiner, M. Am. Soc. C. E.

Scope of the Investigation.

On the Atlantic Seaboard from Maine to Florida there are four harbors which contain ports of importance where coal is discharged directly from commercial coal piers into the hatches of vessels. These harbors are New York, Philadelphia, Baltimore, and Norfolk.

There are 13 ports, embracing 29 coaling plants, in New York Harbor;
3 " " 11 " " " operation and 2 under construction in Philadelphia Harbor;
4 ports, embracing 8 coaling plants, in Baltimore Harbor;
3 " " 8 " " " operation and 2 under construction in Norfolk Harbor;

making a total of 23 ports, embracing 56 plants in operation and 4 under construction. In addition, the construction of new plants, at Baltimore, Philadelphia, and New York, is under consideration at the present time.

During the summer of 1912 the writer was retained to report on the facilities of these plants. With the assistance of his staff, each plant was examined, and investigations were made concerning its output, capacity, cargoes, type, tracks, grades, equipment, construction, and operation. With the consent of his client, the writer submits the

*Presented at the meeting of December 3d, 1913.

substance of his investigations, with the hope that the information collated will be of interest to the members of the Society and of value to those concerned in the delivery of coal to vessels.

The principal data in connection with these piers are given in Tables 1, 2, 3, and 4, wherein the discharge is the maximum estimated capacity.

Output and Capacity.

The domestic and foreign shipments of coal from the various harbors during 1911 are given in Table 5.

Assuming that, on an average, a car contains 42 tons of coal, the tonnage in Table 5 indicates that about 1 050 000 cars were unloaded into boats of various kinds in 1911 from all the coaling ports.

The maximum capacities of the plants are given in Tables 1 to 4, and, as a general rule, are based on the largest number of cars handled in any one day, under favorable conditions of cargoes and deliveries. The average capacities are based on the deliveries obtained under ordinary conditions, where there is more or less delay due to the number and various sizes and kinds of cargoes, and approximate two-thirds of the maximum capacities.

During any of the past 8 years, the ratio of the actual maximum output to the estimated maximum capacities, as indicated in Tables 1 to 4, is about:

51% in New York Harbor;
29% " Philadelphia Harbor;
31% " Baltimore Harbor;
30% " Norfolk Harbor.

If all the ports had worked to their average estimated capacities, they could have discharged their output of 1911 in the following times:

New York Harbor	222	days.
Philadelphia Harbor	185	"
Baltimore Harbor	195	"
Norfolk Harbor	141	"

It will be noted that in New York Harbor the maximum output for any one of the past 8 years developed 51% of the maximum estimated capacity, and Philadelphia, Baltimore, and Norfolk only deliv-

ered about 30 per cent. This apparently better showing in New York Harbor can be explained by the fact that in that harbor there is an almost continuous run of cargoes varying from 50 to 3 500 tons for local consumption, and in other harbors the local consumption from the piers is not nearly as great; also, the cargoes are generally larger and of less frequency.

* Maximum capacity of pier is 140 cars of

On the basis of the estimated maximum capacities of the various piers, the percentages of coal furnished by each of the roads serving would be about as given in Table 6.

From the fact that the actual annual output of these ports represents only from 141 to 222 working days under average capacity for the four harbors, it may be reasonably inferred that the existing

ports are capable of supplying greater demands for coal than now exist; but, of course, it must be remembered that a pier which supplies a succession of small cargoes, and especially to boats not under their own power control, will not be able to work to the same capacity as in cases where there will be the same continuous run of large cargoes regularly, and, though some of the ports may be hard pressed at times to make deliveries satisfactory to urgent demands, there are other ports which are more or less idle a great part of the time, and all the piers are idle some of the time, due to lack of vessels. The necessity of being in a position to furnish large cargoes in a short time requires, in a number of the ports, the construction of piers of greater capacity than they will be required to develop, except at intervals.

The capacity of many of the piers is also restricted by lack of yard facilities, or by lack of proper adaptation for the kind of cargoes handled, the height, in a number of cases, being insufficient to permit of a free discharge of coal from the pockets to the vessels. The piers having the largest estimated maximum capacities per day of 10 hours in the various harbors are given in Table 7.

CARGOES.

In New York Harbor coal is delivered mostly to lighters and barges up to 3 500 tons capacity, there being but few sea-going vessels which are coaled directly from the piers, either in bunkers or in cargoes. These are usually loaded from lighters. Some piers are prepared to furnish coal in from 5- to 10-ton lots, but most of the cargoes delivered are not less than 50 tons.

In Philadelphia Harbor coal is delivered to local tugs, barges, schooners, scows, tramps, and colliers, the greater portion being in barges for domestic use, cargoes running up to 3 500 tons, and to a number of tramps of from 5 000 to 7 000 tons, with an occasional collier of 12 500 tons.

In Baltimore Harbor coal is delivered to small bay craft up to 50 tons, coastwise sailing vessels with cargoes of from 1 500 to 6 000 tons, barges up to 7 500 tons, tramps from 5 000 to 7 000 tons, and colliers of 12 500 tons. A large part of this coal goes to New England and to foreign countries.

In Norfolk Harbor cargoes are delivered to boats of about the same class as in Baltimore Harbor, but some of the Norfolk piers are better adapted for furnishing coal to the largest Government colliers.

The two largest Government colliers, the *Cyclops* and *Neptune*, have a length of 542 ft., beam 65 ft., hatches 32 ft. athwartships, 13 ft. fore and aft; the top of the forward cargo hatch when the boat is in ballast trim is about 30 ft. above the water level, and the aft cargo hatch 25 ft., the bunker hatches being about 38½ ft. When out of

ballast trim, a condition which may occur rarely, the aft bunker hatches may be about 43 ft. above the water line. Their main draft when loaded is 27 ft. 7 in. On account of the steel cranes and derricks on the decks of these boats, it is somewhat difficult to coal them.

The largest coastwise steamer of the New England Coal and Coke Company is the *Malden,* which has a length of 406 ft. over all, beam 54 ft. 6 in., ten cargo hatches 30 ft. athwartships and 15 ft. fore and aft, one bunker hatch 24 ft. athwartships, 7 ft. fore and aft. The distance from the top of the cargo hatches to the water, when the boat is in ballast trim, varies from 26 to 32 ft., and the bunker hatch is 32 ft. It is probable that in the future this company will build colliers up to 550 ft. in length, with from 65 to 70 ft. beam.

Channels and Tidal Variations.

The present depths of the channels leading to the various ports in the four harbors are given in Table 8.

Classification of Coal Plants.

The coal piers constructed for the purpose of supplying coal to vessels in the harbors of the Atlantic Seaboard may be divided into the three general classes:

(A) Gravity Plants,
(B) Mechanical Plants,
(C) Combination Plants.

A.—Gravity Plants.

This name is generally given to coal trestles which are equipped with pockets or bins for receiving the coal from the usual cars, and with chutes for discharging it into vessels moored at the piers. Although a number of these plants have such grades as will permit the loaded cars to drift over the deck tracks and the empties to return to the yards by gravity, there are also a number where the grades are so light that power of some kind is required for the movement of the loads over the deck and of the empties to the yards; but, no matter what the grades or how the cars are moved on the deck and on the return tracks, the pier is classed as a gravity plant if the coal is discharged directly into the pockets or chutes from the regular coal cars on the tracks on top of the pier.

The general class of gravity plants embraces nine types, as shown by Figs. 1 and 2.

Type A1.—Gravity Approach and Return.—The loads are delivered to the pier deck, spotted over the pockets, and the empties returned to the yards, all by gravity. This is the ideal type of gravity plant; but locations where the land back of the dock is at a sufficient elevation for a gravity lead to the pier deck, and where the empty yard can be constructed at an elevation lower than the deck of the pier, are not usual in harbors. As a matter of fact, the writer has been unable to

locate any pier of this type on the Atlantic Seaboard within the limits of the United States. In the Perth Amboy Port of New York Harbor, Piers Nos. 1 and 2, operated by the Lehigh Valley Railroad Company, have a descending grade of 0.6% on the trestle approach and a 1% grade for the return of empties, but as the 0.6% approach grade will not permit cars to move by gravity except under very favorable weather conditions, and as locomotives are therefore used, these piers cannot be considered as meeting the conditions of this ideal type.

Type A2.—Grade Approach and Return.—The pier deck beyond the bulkhead of the slips is at approximately the same elevation as the tracks on the approach trestlework and in the yards, thereby requiring locomotives for delivering the loads on the deck and for removing the empties. The grades may be level, or slightly ascending, or descending. On account of engine service for both loads and empties, on the deck as well as in the yards, the operating cost of this type may be high, the discharge and return of the cars slow, and the capacity of the pier somewhat restricted thereby, especially when there are only one or two tracks on the pier; but as more cars can be handled by a locomotive on easy grades than on steep inclines, the cost of operation of this type may be low, or lower than any of the types where empties are returned by gravity, when the character of the vessels, loads, and their cargoes will not permit of continuous operation. It will depend largely on the number and types of vessels and cargoes. There are two piers of this type in service in New York Harbor and four in Philadelphia.

Type A3.—Grade Approach and Gravity Return.—The pier deck is at approximately the same elevation or grade as the tracks on the approach trestlework, but at a higher elevation than in the empty yard. Loads are delivered on the pier by locomotives and the empties are returned by gravity. This type, on account of the easy delivery grade, where a considerable number of cars can be handled by one locomotive, and the return of empties by gravity, should be economical in operation where conditions are such as to enable its construction without sacrifice of yard facilities and operations, and without an excessive expenditure for the construction and maintenance of long and high trestle approaches. There are only two piers of this type, both in New York Harbor.

Type A4.—Locomotive Incline at the Shore End and Locomotive or Gravity Return from the Shore End.—The pier deck may be level or

have a slight grade. The loads are pushed up the incline by a locomotive and are then handled and the empties removed by the locomotive, or the empties are spotted by gravity or by using pinch-bars and then returned by gravity down the delivery incline, depending on the grades. This is a simple type of so-called gravity pier, and is used where the width of right of way is contracted and local conditions are such as to necessitate the construction of a joint yard for loads and empties within a restricted space. The empties may be returned over the delivery tracks, for piers where the output is small, or over independent tracks, where the output is large and the right of way will permit the additional width necessary for such tracks. There are eleven piers of this type in New York Harbor, five in Philadelphia, and five in Baltimore, making a total of twenty-one now in operation.

Type A5.—Load and Empty Yards at Opposite Ends of Pier.—The loads are pushed from the yard up the incline at one end of the pier, and the empties are returned to the yard at the other end, the entire movement of cars being in one direction. This type may be used along the banks of rivers or canals, where the yards and tracks have to be parallel to the stream, and is used for locomotive coaling stations, but, so far as the writer has been able to discover, there are no piers of this type on the Atlantic Seaboard.

Type A6.—Locomotive Incline at Shore End, Gravity Return from Sea End.—Loads are pushed up the incline to the deck by a locomotive, then drift by gravity over the pockets, and, when unloaded, drop by gravity to a switchback or turn-table, where the movement is reversed to the empty yard. The empty return tracks, being independent of the approach tracks, may be graded so as to reach an empty yard adjoining the load yard or at almost any convenient location, without impeding operations. All things considered, this type is perhaps the most practical and economical of the gravity plants, both as to cost and operation, and is sufficiently flexible to meet a diversity of local conditions. There are four piers of this type in New York Harbor, two in Philadelphia, two in Baltimore, and six in Norfolk, making a total of fourteen now in operation. The Baltimore and Ohio pier at Curtis Bay, Baltimore Harbor, is a well-known example.

Type A7.—Locomotive Incline at Sea End, Gravity Return from Shore End.—This is simply a modification of Type A6. The lead for the yard tracks is nearer the water and the empty yard is farther back

than in Type A6. The deck of the pier has an ascending grade toward the sea end, thereby making the highest part of the deck at the place where it is of most service. There are no piers of this type in operation, so far as can be learned by the writer, but the advantages of the type in certain locations make it worthy of consideration.

Type A8.—Power Incline at Shore End, Gravity Return from Sea End.—The pier has a down grade toward the sea. Cars are pulled up the incline by a cable and stationary engine, or are pushed up by a small car or barney attached to the end of a cable. Otherwise the operation is the same as in the locomotive incline, Type A6. The power inclines, with their steep grades, are adaptable to locations where the space at the approach to the pier is not sufficient for a locomotive incline. The delivery track from the loaded yard is usually graded downward so as to feed the cars to the foot of the incline by gravity. There are four piers of this type in New York Harbor, one in Philadelphia, one in Baltimore, and one in Norfolk, making a total of seven, exclusive of a similar plant in combination with a mechanical plant, which is embraced under another classification.

Type A9.—Power Incline at Sea End, Gravity Return from Shore End.—The pier has an up grade toward the sea, and is simply a modification of Type A8. The highest part of the deck is at the sea end, where the highest chutes properly belong. This type, when vessels are loaded from only one side of the pier, is well adapted to localities where the load yard is close to the pier. When piers deliver coal to vessels on both sides, the delivery track can be placed in the middle and the deck tracks can be carried across the entire width of the pier, except for the space required for the incline through the deck, thereby requiring less width of pier at the shore end than for Type A8. There are no piers of this type in operation on the Atlantic Seaboard, but it is worthy of consideration in favorable locations.

B.—Mechanical Plants.

Coaling plants which are equipped with car-dumping machinery, elevators, conveyors, etc., for delivering coal to vessels without the use of high and long trestles, are classed as mechanical. The car-dumping machines pick up the loaded cars and dump their contents on an apron, from which it flows into vertical chutes which are adjustable and kept full of coal so as to reduce the fall and breakage. These

machines vary somewhat in design, and are manufactured by the McMyler Manufacturing Company, the Wellman-Seaver-Morgan Company, the Brown Hoisting and Conveying Machine Company, all of Cleveland, Ohio. A description of the several types of mechanical plants (Figs. 3 and 4) follows:

B1.—Car-Dumping Machine at Grade.—The loaded car is delivered near the cradle of the machine, which is at grade or only a slight elevation above it, and is placed or hauled on the cradle. It is then lifted vertically and dumped into chutes by turning it over sideways. The car is then lowered, pushed off the cradle by the next loaded car entering, and hauled away. The range of delivery to vessels is confined within the sweep of the chutes, and this necessitates moving the vessels while being loaded. This type is adapted to locations where space is restricted to such an extent that the gravity movement of empty cars is impracticable, but there is no plant of this particular type in operation on the Atlantic Seaboard.

B2.—Car-Dumping Machine with Power Incline.—The loaded car is delivered by gravity or locomotive to a barney or cable connection which moves up a steep inclined plane to the cradle of the machine. It is then dumped into chutes by turning it over sideways, and the empty car is returned to the yard by gravity. This type requires more space than B1, and, as the cars are delivered at an elevation, the vertical lift of the machine need not be as great. When space is available, this plant is more economical of operation than Type B1. There are five plants in New York Harbor and one in Philadelphia, a total of six on the Atlantic Seaboard, exclusive of those used in combination with gravity piers and included in Class C.

B3.—Car-Dumping Machine with Conveyors.—The machine turns the car over sideways and dumps the coal into conveyor buckets which carry it from the machine and lower it to the bottom of the hatch before dumping. The cars may be handled by locomotives or by barneys and gravity. It is claimed that this will reduce the breakage of coal to a minimum. There are no plants of this type on the Atlantic Seaboard, but one is in operation at Buffalo, N. Y.

B4.—Car-Dumping Machine with Movable Tower.—The loaded car is delivered by a locomotive or by gravity to a barney, which moves it up an inclined plane to the cradle of the machine. It is then dumped into a self-propelling transfer car having a sloping bottom and dis-

charge, which moves on to a movable tower. The tower moves on tracks running along the pier, and elevates the body of the transfer car vertically to the proper height; then the coal flows from the side of the car into chutes. The body of the transfer car is then lowered to its tracks. The empty transfer cars return for another load and the empty coal cars are returned to the yard by gravity. This type is very

elastic and will deliver coal at any part of the pier without moving the vessels. When provided with a mechanical trimmer, as indicated on the sketch (Fig. 1), the cost of trimming coal may be reduced considerably. There are as yet no plants of this type in operation on the Atlantic Seaboard, but a number of designs have been under consideration.

charge, which moves on to a movable tower. The tower moves on tracks running along the pier, and elevates the body of the transfer car vertically to the proper height; then the coal flows from the side of the car into chutes. The body of the transfer car is then lowered to its tracks. The empty transfer cars return for another load and the empty coal cars are returned to the yard by gravity. This type is very

FIG. 4.

elastic, and will deliver coal at any part of the pier without moving the vessels. When provided with a mechanical trimmer, as indicated on the sketch (Fig. 4), the cost of trimming coal may be reduced considerably. There are as yet no plants of this type in operation on the Atlantic Seaboard, but a number of designs have been under consideration.

B5.—Endless Chain Conveyors.—The coal is dumped into a hopper and then elevated by an endless chain conveyor to such a height that the coal will run into bins and be delivered to the hatches through chutes. This type is indicated in particular cases where the local and congested conditions will not permit of sufficient space to turn the cars so that they may be run on the piers, as in cases where the supply track runs at right angles to the pier and close to the shore end. There is one plant of this type in New York Harbor at the end of a pier in the Hoboken Port of the Delaware, Lackawanna and Western Railroad.

C.—Combination Plants.

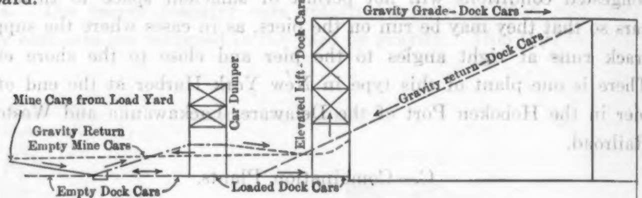
It is quite possible and practicable to combine car-dumping machines with gravity piers in a variety of ways. Two of these combinations are described, as follows:

Type C1.—This type is a combination of a car-dumping machine (power incline and gravity return of empty mine cars) with an elevator lift to a gravity pier deck at the shore end for special dock cars, and a gravity return of empty dock cars from the sea end. The mine cars are dumped by the machine into special dock cars which move by their own power, or by gravity, to the platform of the elevator, are then raised to the deck of the pier, over which they move by their own power, or gravity, and discharge coal into the pier pockets and chutes, and then return under brake control to the car dumper. The empty mine cars which have been unloaded by the car dumper return by gravity to the empty yards. Two plants of this type are under construction in Norfolk Harbor, one at Lamberts Point and the other at Newport News. See Fig. 5.

Type C2.—This type is a combination of car-dumping machine (power incline and gravity return of empty mine cars) with Type A8, a gravity plant power incline for special dock cars at the shore end and a gravity return of these cars at the sea end. In this type the dumping machine empties the mine cars into a special dock car, these special dock cars are pushed to the top of the pier over the barney incline, and are then dropped by gravity, or under their own control, to the pockets where the coal is delivered; they are then returned to the car dumper under brake control over the gravity return. The empty mine cars drift by gravity over the switchback to the empty

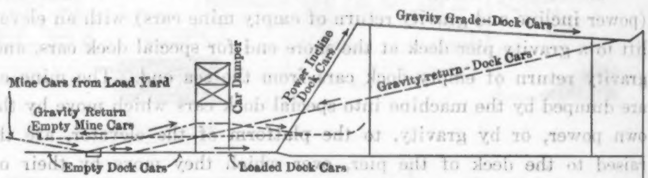
yards. There is one pier of this type in Norfolk Harbor at Sewells Point. See Fig. 5.

Table 9 shows the number of each class and type of plant now in operation or under construction in the harbors of the Atlantic Seaboard.



TYPE C 1

CAR-DUMPING MACHINE (POWER INCLINE AND GRAVITY RETURN OF EMPTY MINE CARS) WITH ELEVATOR LIFT TO PIER DECK AT SHORE END FOR SPECIAL DOCK CARS, AND GRAVITY RETURN OF EMPTY DOCK CARS FROM SEA END.



TYPE C 2

CAR-DUMPING MACHINE (POWER INCLINE AND GRAVITY RETURN OF EMPTY MINE CARS) WITH TYPE A 8, GRAVITY PLANT, POWER INCLINE FOR SPECIAL DOCK CARS AT SHORE END AND GRAVITY RETURN OF SPECIAL DOCK CARS FROM SEA END.

Fig. 5.

Dimensions.

The longest coal pier, measured from the bulkhead to the end of the slip, is Pier No. 1, Pennsylvania Railroad Company, at South Amboy, N. J., which has a length of 1 800 ft. The length of the Curtis Bay pier of the Baltimore and Ohio Railroad is 800 ft., of the Norfolk and Western pier at Lamberts Point, 867 ft., of the Virginian Railway pier at Sewells Point, 1 000 ft., of Pier No. 12 of the Chesapeake and Ohio Railway at Newport News, 850 ft., and of Pier No. 6 of the Pennsylvania Railroad at Greenwich, Pa., 735 ft. These represent the lengths of the slips. The two piers at Norfolk now under construction, one for the Norfolk and Western Railroad and one for the Chesapeake and Ohio Railroad, will have slips 1 200 ft. long.

* One plant under construction and four in service.

† Under construction.

The highest pier thus far built is the Norfolk and Western Pier No. 3, at Lamberts Point, which has a height of 70.4 ft. above the water near the sea end. The Curtis Bay pier of the Baltimore and Ohio Railroad has a height of 59 ft. near the sea end, the Virginian Railroad pier at Sewells Point has a height of 69.2 ft., and the two piers under construction at Lamberts Point and Newport News will have a height of about 91½ ft.

The heights and lengths of all piers on the Atlantic Seaboard are noted in Tables 1 to 4. The highest piers, namely, those under construction at Newport News and Lamberts Point, will have a maximum height of 47 ft. from the discharging end of the chute to the water, and a minimum of 5 ft.

The dimensions of the largest U. S. naval colliers and coastwise steamers carrying cargo coal are given under the heading, "Cargoes." In order to coal freely into coastwise boats, the maximum height of hatches being 32 ft., the height of piers should not be less than 65 ft. above mean tide, when the pier is not provided with storage bins, and, if bins are provided for storing one car of coal each, the height should be at least 70 ft. above mean tide. For coaling the largest Government colliers freely, the height should be at least 8 ft. greater than the foregoing, and to meet the possible conditions when the boat is out of ballast, the height should be at least 13 ft. greater.

Piers with heights 5 ft. less than those given will coal to the same class of boats, but not freely, because the chutes will be inclined at too flat an angle for the gravity flow of coal. A pier only 50 ft. high above mean tide can be made to deliver coal to some of the coastwise steamers with capacities up to 7 000 tons, but at extra expense for handling and trimming. As a general proposition, for efficient service to boats of all classes, the height of a pier should be from 33 to 43 ft. greater than the height of the highest hatches of vessels coaling at the ports, depending on the type of chute used and the storage capacity of the bins.

Tracks and Grades.

The tracks leading to piers and yards are usually arranged so as to require the least number of shifting operations. In some yards a large number of short tracks are required to sort cars with different kinds of coal, and when this is the case, the load yard, when practicable, consists of a number of short tracks, or a gridiron arrangement with a ladder at each end. For the empty-car yard, sorting is generally not necessary, and a few long tracks are used. The approach tracks to locomotive inclines usually have as great a length as the situation will permit, in order to enable locomotives to have a good run for overcoming the grade of the incline. The approach tracks leading to barney inclines have a down grade where the conditions will permit, in order that the cars may drift by gravity to the barney. Tracks on the piers are arranged in a number of ways, depending on the local conditions, the type of pier, and whether coaling is done from one or both sides.

The grades on locomotive inclines vary from 1 to 5 per cent. There are only three piers having grades of 5%, six with grades from 3 to 3½%, and twenty-six with grades less than 3 per cent. The conditions which affect the choice of the grade are: longitudinal space, capacity of the locomotive to be used, the required discharging capacity of the pier, and economy of operation and cost. A steep locomotive incline will cost less to construct, but usually more to maintain and operate, than an easy or moderate grade, and, as the delivery of the coal to the pier deck should keep pace with the discharge into vessels, for economical operation, the grade should not be such as to retard delivery. The selection of the grade on locomotive inclines is an important matter, and should be determined, not so much from what is

in use on other piers as by a study of the local conditions and requirements for each case, and when conditions permit, it should not exceed 3 per cent.

The grades on barney or cable inclines to gravity class piers vary from 16 to 25%, and on mechanical classes from 11 to 12 per cent. It will require less power and less expensive machinery to pull a car up a 12% grade than up a 25% grade, and though the steeper inclines are usually resorted to on account of limited longitudinal space, it is economy to use the easiest grade permitted by the local conditions—economy even in first cost—as the additional cost of the longer low-grade trestle is often offset by the cost of less expensive machinery, and there is less danger of accident. In mechanical classes of plants, as the inclines are required for relatively small height, it is not necessary to give them a very steep grade. A 16 to 18% grade on a gravity plant, and 10 to 12% on a mechanical plant, appear to be reasonable.

The grades on pier decks vary from 0.5 to 1.5 per cent. When the grade is less than 1%, a short, sharp grade is sometimes introduced to give an impetus to the cars at the head of the pier and at the switch-back. The object of a grade on the pier deck is to enable cars to move slowly by gravity. In the summer cars in good condition will run freely on an 0.8% grade without resort to pinch-bars. As coal is delivered to vessels during cold as well as warm weather, and in northern as well as southern climates, the selection of a grade for any pier is more or less a matter of compromise; grades from 1 to 1.3% give good results in New York, but grades from 0.67 to 0.76% appear to give equally good results in the South when headed by a sharp starting grade.

Grades for the return tracks vary from 0.6 to 5% for hand-brake control, but it is considered good practice to keep them less than 2% when practicable, and to ease them off as their lower ends approach the empty yard. The percentage of grade of the return track is governed to a considerable extent by the location of the empty yard.

All changes in grade are eased by vertical curves extending for a distance of from 35 to 50 ft., and even for a longer distance where circumstances warrant, depending on the degree of change and the length of grades. The number of tracks on approaches, including deck and empty return, with their grades, are given in Tables 1 to 4.

Switchbacks and Pivot Tables.

Switchbacks are intended to work automatically, and have grades and lengths proportioned so as to keep the empty cars moving by gravity. They are generally constructed with adjustable blocking, in order that the grades may be quickly adjusted during the different seasons of the year, as those having grades satisfactory for handling cars by gravity in hot weather will not operate well in cold weather and *vice versa.* The grades, etc., of a typical switchback are indicated on the sketch, Fig. 6.

In some cases, where longitudinal space will not permit the construction of a switchback, counterbalanced transfer or pivot tables are used. The normal position of the table is in line with the delivery track. Cars are run on the table by gravity, and the table moves by gravity to a connection in line and grade with the return track, the empty car then leaves the table by gravity, and the table is returned to its normal position by the counterweight. Pivot tables of this character are in use at Lamberts Point, Piers Nos. 1 and 2, in Norfolk, and at Port Covington and Clinton Street, in Baltimore. One man is required at each table to control the brake levers governing the movement of the table. The arrangement of a typical table is shown on the sketch, Fig. 6.

Wherever there is sufficient space for the construction of a properly designed switchback, it is preferable to a pivot table, as it has less mechanism to get out of order and is equally effective.

Equipment.

The equipment in connection with the gravity type of pier as herein discussed embraces bins, pockets, chutes, and power-incline mechanism, and, for all classes of piers, scales and thawing plants.

Bins and Pockets.—For the purposes of this paper, the following classification of bins and pockets on coal piers has been made:

Bins.—Hoppers or receptacles constructed for the purpose of storing coal temporarily or permanently;

Pockets.—Hoppers constructed to receive the coal from the cars and to deliver directly into the chutes without storage.

There are various forms of construction of bins and pockets; a general description of each follows.

Bins in most cases consist of partitions framed to timber bents of the approach trestle; they have wooden floors, and the coal is dropped from the car bottoms through openings in the deck. In some instances these bins are constructed with enclosed sides and with a hopper bottom, so that the coal may be reloaded into cars or loaded into wagons

TYPICAL SWITCHBACK AND PIVOT TABLE

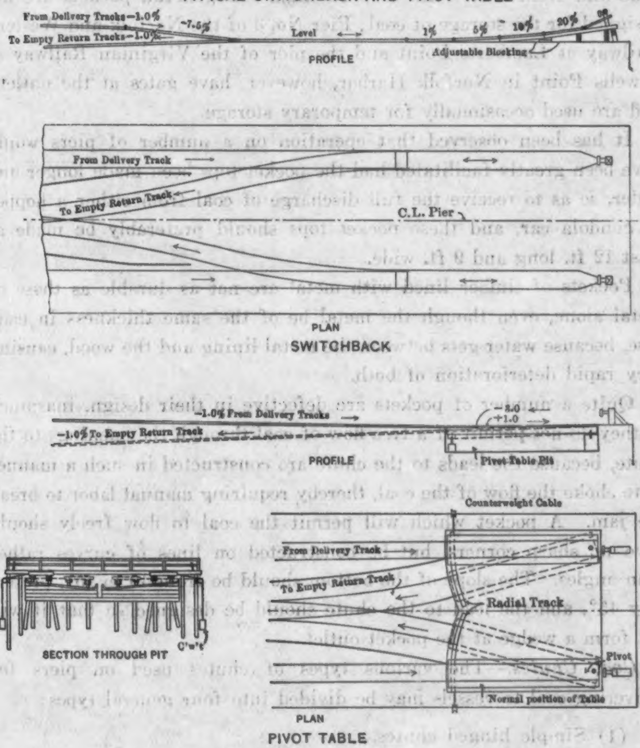

FIG. 6.

or boats through chutes. When bins have sides and hopper bottoms they are usually lined with sheet metal.

Pockets are ordinarily used to receive the coal as it drops from the hopper bottom of the car and convey it to the chutes. Pockets are located under the delivery tracks on the pier, and have their bottom outlet at the side of the pier from 8 to 12 ft. below the deck.

Most of the piers examined were equipped with timber pockets, metal lined, although the pier of the Virginian Railway at Sewells Point in Norfolk has metal pockets. The upper ends of the pockets are generally about 9 ft. long, and from 5 to 9 ft. wide, the sides and bottom tapering to an opening at the side of the pier about 4 ft. 6 in. wide and from 2 ft. 6 in. to 3 ft. high. In general, pockets are not designed for the storage of coal; Pier No. 3 of the Norfolk and Western Railway at Lamberts Point and the pier of the Virginian Railway at Sewells Point in Norfolk Harbor, however, have gates at the outlets, and are used occasionally for temporary storage.

It has been observed that operation on a number of piers would have been greatly facilitated had the pocket tops been made longer and wider, so as to receive the full discharge of coal from either a hopper or gondola car, and these pocket tops should preferably be made at least 12 ft. long and 9 ft. wide.

Pockets of timber lined with metal are not as durable as those of metal alone, even though the metal be of the same thickness in each case, because water gets between the metal lining and the wood, causing very rapid deterioration of both.

Quite a number of pockets are defective in their design, inasmuch as they do not permit of a free flow of coal through the openings to the chute, because the leads to the chute are constructed in such a manner as to choke the flow of the coal, thereby requiring manual labor to break the jam. A pocket which will permit the coal to flow freely should have no sharp corners, but be constructed on lines of curves rather than angles. The slope of the bottom should be from 40 to 45°, preferably 45°, and the lead to the chute should be designed so that it will not form a wedge at the pocket outlet.

Coal Chutes.—The various types of chutes used on piers for delivering coal to vessels may be divided into four general types:

(1) Simple hinged chutes,
(2) Hinged chutes adjustable at the upper end,
(3) Hinged chutes with telescopic leg at the upper end,
(4) Chutes with telescopic leg at the lower end.

Some of these types are patented, and have different trade names, according to the notions of the patentees, but the foregoing general classification will best serve the purpose of this paper. Fig. 7 contains

sketches showing the general characteristics of the four types. A description follows:

Type 1.—Simple Hinged Chute.—This is the simplest type, and is installed on the majority of piers having a number of chutes along the side. The chute is of metal, or of timber with a metal lining. It is hinged to the coal pocket outlet, may be swung to any desired vertical angle about the fixed horizontal hinge, and in some cases has been designed with a pivot arrangement to allow a lateral swing also. The coal drops freely from the outer or lower end of the chute into the hold of the boat. The dimensions of these chutes are dependent to a large extent on the general size of the pier and the class of vessels coaled, and are largely based on the judgment of the different designers, but the most common dimensions are approximately as follows: width at hinge 5 ft. 6 in., width at lower or free end 4 ft. 6 in., depth at hinge 18 in., depth at lower or free end 10 in., the length varies from 12 to 30 ft. On several piers chutes of this type are counterbalanced by chains or cables attached to hanging weights, the counterweight chain or cable being operated over a differential drum fastened to the drum shaft of the operating winch. Chutes of this type are operated by hand winches, and in general, when not counterweighted, it requires the services of one man for about 5 min. to lower and adjust a chute from its full vertical position to the position ready to discharge coal into a vessel, and it takes four men about 5 or 6 min. to raise a chute to its full vertical position. When the chutes are counterbalanced or over-counterweighted, these operations may be accomplished by a less force and in less time. The general design indicated by Type 1, Fig. 7, is typical, but there are a number of modifications for handling and counterbalancing, all more or less effective, some of which are patented.

Type 2.—Hinged Chute Adjustable at Upper End.—This chute is a simple apron essentially as described for Type 1, but its upper end is hinged to a metal frame which slides through a vertical guide attached to the frame of a fixed vertical leg. The chute receives the coal directly from the vertical leg, which is fed from the pockets. The vertical leg is of metal, or wood with metal lining, and has several regularly spaced openings for discharge into the chute. Each of these openings is provided with a hinged plate which can be swung into a vertical position to close the opening in the side of the vertical chute, or down into an inclined position to form a floor for the vertical leg

at the opening from which it is desired to discharge. This type allows a vertical adjustment of the apron, so that coal can be delivered to the hatches of boats without too great a drop from the outer end of the apron. It is known as the Henkel patent. The vertical adjustment of the upper end, and the adjustment of swinging the apron through its vertical angle are both made by hand winches. This chute is sometimes counterweighted for both the upper and lower ends, in a manner similar to that for Type 1. The power necessary to handle and adjust this type is considerably more than for Type 1, as it requires two men about 5 or 6 min. to lower the upper end of the chute from the highest to the lowest pocket outlets, and four or five men from 12 to 20 min. to reverse the movement. In addition to this, it takes about the same number of men and the same time to swing the apron through its vertical arc, as described for Type 1. Type 2, Fig. 7, illustrates this chute. It is used on the piers of the Philadelphia and Reading Railroad at Port Richmond in Philadelphia Harbor.

Type 3.—Hinged Chute with Telescopic Leg at Upper End.—This chute is a simple apron, as described for Type 1, but its upper end is hinged to a vertical telescopic leg, which receives the coal directly from the pocket and discharges into the inclined chute. The front or slip side of the vertical leg is open, and a movable hopper, to which the apron is hinged, can be adjusted vertically throughout the length of the leg. A series of sliding plates, resting on the top of the movable hopper and sliding in guides in the front face of the leg, closes the front face of the vertical leg as the hopper is lowered. The leg being adjustable as to vertical height, and the inclined chute being hinged thereto, makes it more flexible than either Types 1 or 2, and though the coal falls freely from the outer end of the inclined chute, the height of the fall can be reduced or increased by adjusting the vertical leg. These chutes are operated by hand winches, and the time and number of men required to lower and raise the inclined chute are the same as for Type 1; and, in addition, it requires one to two men from 5 to 10 min. to adjust the movable hopper from the highest to the lowest positions, and from four to five men from 10 to 30 min. to reverse this latter operation. These chutes are generally all of metal, and in most cases both the inclined and vertical chutes are counterweighted. This type is patented and generally known as the Link Belt Chute. It is illustrated by Type 3, Fig. 7. They are used on

FIG. 7.

Pier No. 6, Pennsylvania Railroad, at Greenwich, Philadelphia Harbor, Curtis Bay pier and Port Covington pier, in Baltimore, and the Virginian Railway pier at Sewells Point, in Norfolk. The inclined chutes on the Sewells Point pier are pivoted so as to allow the lower end of the chute to swing through a horizontal arc of 12½ ft. on each side of the center line, or a total of 25 ft.

Type 4.—Chute with Telescopic Leg at Lower End.—This type consists of a vertical telescopic chute attached to the outer end of an inclined apron. The coal slides down the apron into the vertical chute and into the hold of the vessel. It is of metal, the lower end of the inclined apron being covered and the lower end of the vertical telescopic chute having a gate so that the chute can generally be kept full of coal in order that it will flow in an unbroken stream from the lower mouth of the chute without excessive fall. The vertical telescopic leg is generally pivoted to the apron near its upper end, so that the lower end can be swung to deliver to the sides as well as to the middle of the hold, and in this way save in the amount of trimming. Generally, the vertical leg is adjustable through a range of 13 ft., and, in addition, the apron is adjustable through a vertical range of 32 ft., so that the arrangement is readily adapted for any reasonable depth of hold or height of hatches. This chute, being very heavy, requires mechanical power for its operation. A number of the mechanical plants in New York Harbor are equipped with chutes of this type. Type 4, Fig. 7, indicates its general construction and adaptability.

These four general types embrace all the chutes now in use on piers on the Atlantic Seaboard. There are numerous modifications, however, some of which have been put into actual use on coal piers in some of the Great Lake ports. A modification of Type 1 is shown on the sketch of the car dumper, Fig. 4. This is a simple hinged chute with a telescopic extension at its lower end.

The movable tower, Fig. 4, is a modification of Type 4, to the lower end of which has been added a horizontal arm capable of being swung in a horizontal arc, which distributes the coal to any part of the hold. The device is known as an automatic trimmer, but, as far as the writer can ascertain, it has not yet been used.

In general, the height of the pier and the design of the chutes are, to a great extent, the limiting factors for any one pier, because, on the height of the delivery end of the chute depends the size of the

boats that can be coaled at that pier, without excessive costs for handling the coal. It is usually recognized that the angle of repose for anthracite coal is about 27° with the horizontal and for bituminous coal about 35° with the horizontal, and the chutes should be designed to discharge to the boats so that the delivery end will allow a free flow into the hold without requiring shoveling in the chute, and this will necessitate an inclination of the chutes of somewhat greater angles than those mentioned. Tests show that coal flows on metal chutes at a less angle in summer than in winter, and, in general, the inclination of the chute should never be less than 35° for bituminous, and that the best results are obtained when the chutes are inclined from 40 to 45 degrees.

Relative Merits of the Four Types of Chutes.—The qualities which determine the relative merits of the several types used on gravity plants are:

(1) Simplicity of mechanism and adjustment,
(2) Area of distribution,
(3) Speed of delivery,
(4) Quantity of breakage,
(5) Cost of installation,
(6) Cost of operation,
(7) Cost of maintenance.

The fixed-hinge chute, Type 1, has the merit of simplicity, speed of delivery, and relatively low cost of installation and maintenance. Its area of distribution is generally contracted. The cost of distributing after delivery into the hold, and the damage of the coal due to excessive breakage, may offset, to a large extent, the merits which it possesses. This type, however, is used on a large majority of piers. The cost of a metal chute, erected in place, with counterweight and winches, will vary from $800 to $1 000.

The hinged chute, adjustable at the upper end, Type 2, and the hinged chute with telescopic leg at the upper end, Type 3, have the merit of distributing delivery and small breakage, but the greater cost of installation, operation, and maintenance may offset their merits, to some extent, depending on the commercial conditions under which the coal is handled. The complete cost of this type, connected to the vertical legs on the pier, varies from $1 500 to $1 600.

A number of devices have been patented and tried on the ends of fixed chutes, with an idea of reducing the breakage of coal, giving a greater distribution for gravity piers, but most of them have been discarded because they were cumbersome and slow, or wore out quickly; in cases where they have been meritorious they have been discarded on account of lack of interest by the pier management, which may have felt that the quick release of vessels, a large daily tonnage, and consequent reduction in pier operating expenses, will be more important to the railroad interests than the loss in the value of the coal to the customers due to the breakage. The question is really a commercial one for each pier, as to whether the railroad's interests are or are not best served by the increased expense of installing and maintaining chutes which deliver the coal with the least breakage.

The chute with the telescopic leg at the lower end, Type 4, because of its weight, is adaptable mainly to mechanical plants or on gravity piers equipped with mechanical power for handling the chutes. This type has the merits of wide distribution, speed, and least breakage; but, for gravity piers, has a high cost of installation, operation, and maintenance, and is cumbersome in handling. The merit of distributing the coal over a considerable area, thereby reducing the cost of hand trimming is a commercial factor to be weighed against the cost of installation and of maintenance and power for operation.

On account of the varieties of bituminous coal handled from piers, different arrangements have to be provided in the various ports. In Norfolk Harbor the coal handled is the Pocahontas variety, nominally hard and lumpy, with little dust. It may be dropped from greater heights than is permissible for other varieties, and will not be badly broken. On account of breakage, particular care has to be taken in ports where soft grades of coal are handled, especially for foreign shipments.

Track Scales.—Track scales are provided wherever the business requires that the coal be weighed. They are placed at a practical location on the delivery track on the ground or pier, or at the entrance of the load yard. Empty cars are seldom weighed, but, when necessary, this may be done on the general yard scales. There is only one pier where a scale was installed on the empty return track to weigh empty cars, and it has been abandoned.

In most cases the scales are located so as to require the least shift-

ing of the cars, and be convenient for observation and the concentration of the clerical forces. Their lengths are such as to meet the requirements of the standard length of cars used, the running speed while being weighed, and whether cars are weighed while coupled or while moving singly. The standards in use by the various roads vary from 32 to 60 ft. for scales not fitted with automatic weighing devices, and from 34 to 46 ft. for those fitted with such apparatus. On the two new piers now in course of construction in Norfolk Harbor, scales 68 ft. long, with automatic weighing devices, are contemplated. The weighing capacities of the scales on the piers and in the yards in the various ports vary from 160 000 to 300 000 lb. About one-half of the scales investigated were equipped with automatic weighing devices.

Scales must have unyielding foundations, ample strength, and capacity in excess of the ordinary requirements, in order to withstand the constant use and vibrations without having their accuracy destroyed.

Power Incline Mechanism.—The equipment for a power incline usually consists of a couple of boilers, an engine, and a cable running over pulleys and drums generally attached to what is called a mule, which is arranged so as to push the car up the incline to the deck. In one instance—the pier of the Virginian Railway Company at Sewells Point, Norfolk Harbor—electrical power is used instead of steam. Some of the power inclines are not equipped with a mule, but a cable is attached directly to the front end of the car, which is pulled up instead of being pushed. The mule arrangement is considered safer for operating purposes, and requires less inspection of the draw-bars and car mechanism than the cable haul. The complete mechanical equipment, installed, will cost about \$17 000 for a 16% incline, or \$25 000 for a 25% incline.

Coal-Thawing Plants.—Three types of plant for thawing frozen coal are in use. One is simply the thawing of coal in cars while on the pier deck or in the yard by steam jets inserted in the coal, steam being furnished from a locomotive or from independent boilers. In the second type the coal is also thawed by jets of steam, but the plant is installed permanently in sheds. The third type is somewhat elaborate, the coal being thawed under cover by hot air.

As thawing is required only during severe weather, and then possibly only for short seasons, it is, at a number of piers, not considered

of sufficient importance to justify the expense of installation, and in such places frozen coal is broken by hand.

There are nine plants of the first type, located at Elizabeth, Hoboken, Weehawken, and Guttenberg, in New York Harbor, Greenwich port, in Philadelphia, Port Covington, in Baltimore, and Lamberts Point, Sewells Point, and Newport News, in Norfolk Harbor. There is one of the second type at Edgewater, and one of the third type at South Amboy, in New York Harbor.

Construction.

The construction of most gravity piers is of a temporary character, and consists of pile foundations and framed timber superstructure. Judging from the fact that a large number of these piers do not at present meet the increased requirements, their temporary character of construction was apparently justified. Some of the more modern ones, however, such as those at Sewells Point and Lamberts Point (Piers Nos. 2 and 3), Norfolk Harbor, are constructed in a permanent manner over the length of the dock, but such construction was practically made necessary because of their great height and large capacity. The piers under construction by the Norfolk and Western at Lamberts Point, and the Chesapeake and Ohio at Newport News will also be of permanent construction.

As the cargoes, operating conditions, and possible future developments are at present better understood, the modern pier, in order to meet existing conditions and anticipated developments, should be built in a more permanent manner than heretofore, so as to secure the necessary stability under the more severe operating conditions and as a precaution against danger of destruction by fire.

Operation.

The direct cost of operating a pier includes clerical force, policing, engine service, expenses for running the machinery, and the labor of dumping cars and trimming coal. The items of interest on investment, maintenance of plant, and depreciation are also proper charges which affect materially the cost of handling coal, and though not herein considered part of the operating expenses, they are fully accounted for under the heading, "Relative Merits of Different Classes and Types." The items of expense due to general office, supervision, yard, and tugboat service have not been considered in this paper, as they have no important bearing on its object.

Clerical Force and Policing.—The expenses of office force and policing vary somewhat with the capacities of the plants. On one gravity plant investigated these charges in 1911 amounted to \$8 068 for clerical force and \$1 416 for policing, a total of \$9 484 for an output of 2 078 321 tons, making an average cost per ton of about 0.46 cent. During that year the pier worked to about 90% of its estimated average capacity, or at the average rating of 180 cars per day for 270 days. If it had worked to its full average capacity of 180 cars for 300 days, the cost per ton would have been about 0.42 cent, and if it had worked to a capacity of 200 cars per day for 300 days the cost per ton would have been 0.38 cent. This cost of 0.38 cent per ton, therefore, may be considered a reasonable charge for clerical force and policing on a pier working to a normal capacity of 200 cars per day. When working to 75% of the normal capacity, the cost would be about 0.50 cent per ton.

Engine Service.—A locomotive incline type of pier working to an average capacity of 200 cars per day requires the constant use of one locomotive for pushing the cars from the yard to the pier deck. The average charge for an engine which will do the work effectively will approximate \$43 per day, the cost being made up of the following items:

Repairs	\$10.94	
Miscellaneous expenses	1.64	
Interest on cost, \$13 500 at 5%	1.85	
Depreciation " " "	1.85	\$16.28
Coal, 8 tons at \$1.00	\$8.00	
Lubrication	0.24	
Water	0.77	
Other supplies	0.31	
Engine-house expense	0.70	10.02
One engineer	\$4.00	
One fireman	2.50	
One conductor	3.60	
Two brakesmen at \$3.30 each	6.60	16.70
Total daily charge against operation		\$43.00

This engine service would amount to $12 900 per year of 300 working days, or about 0.51 cent per ton, on the basis of an average car load of 42 tons. For piers of the barney incline type, or mechanical type, where the yard is arranged so as to permit the loaded cars to drift by gravity from the yard to the barney pits, no engine service will be required, but, when not thus arranged, one engine will be required for bringing the loaded cars to the barney, at a cost of 0.51 cent per ton.

Expenses of Operating Machinery.—On the power incline type of pier, with a 22% grade, and developing a capacity of 200 cars per day, the daily charges for operating the haulage system (not including dumping cars or engine service) will be about as follows:

Coal, 6 tons at $2.50............	$15.00	
Oil, water, light, etc............	3.25	$18.25
One engineer..........................	$4.00	
Two firemen at $2.40..........	4.80	
Two signal men " 2.00..........	4.00	
Four car riders " 2.00..........	8.00	
One general man " 2.40..........	2.40	23.20
Total daily charge..................		$41.45

This is equal to a cost of 0.49 cent per ton. If the plant should work to only 75% of its average daily capacity, the cost per ton would be about 0.60 cent, assuming that only the coal consumption is reduced.

On a modern mechanical car dumper, operated by steam, with an average capacity of 200 cars per day, the daily cost for operating the machinery, including dumping cars, but exclusive of the engine service, will be about as follows:

Coal, 15 tons at $2.50...........	$37.50	
Oil, water, incidentals, etc........	8.00	$45.50
One engineer....................	$4.00	
Two firemen at $2.40...........	4.80	
One cradle and apron operator....	3.00	
One car handling machinery.....	3.00	
One chute operator...............	2.50	
Four car riders at $2.00.........	8.00	25.30
Total daily charge..............		$70.80

This is equal to a cost of 0.84 cent per ton. If the plant should work to only 75% of its average daily capacity, the cost per ton would be about 0.98 cent, assuming that only the coal consumption is reduced.

Labor of Unloading Coal.—On gravity piers, with a maximum capacity of 300 cars per day and an average of about 200 cars per day, it requires about eight gangs of eight men each on the deck, and one general foreman, for unloading 8 cars at a time into boats in two slips. It takes one gang about 2 min. to dump a car of coal, under the most favorable conditions, and as many as 45 min. when the coal is frozen. In general, 3 cars per chute per hour is considered good work.

On some piers the unloading of the coal after the cars are placed on the deck is done by agreement with the men on the basis of a unit price per car. At a pier in New York Harbor, average capacity 150 cars per day, a car of any size is unloaded for $1, or at about 2.38 cents per ton. At a pier in Philadelphia Harbor, average capacity 100 cars per day, cars are unloaded at the following rates:

60 000-lb. wooden gondolas, $1.00 = 3.73 cents per gross ton.
100 000 " self-dumping cars, 1.50 = 3.36 " " " "
115 000 " steel gondolas, 2.00 = 3.88 " " " "

On a pier in Baltimore, average capacity 180 cars per day during 1911, the cost for labor alone in dumping cars was 1.89 cents per ton. This may also be considered a reasonable price for a pier of the locomotive incline type, working up to a normal capacity of 200 cars per day, and the cost will be the same for a pier of the power incline type. For mechanical plants which dump the cars bodily, the cost of unloading is included in the cost of handling the plant.

Trimming Coal.—Trimming is usually paid for by the hour, and the cost will depend largely on the ruling wages, the type of chutes on the pier, and the character of the vessels loaded. For simple hinged chutes, which practically do no distributing, there is necessarily more trimming than for those which are telescopic and adjustable. The cost of trimming for one large plant in Baltimore Harbor during 1911 was 3.42 cents per ton. In general, where trimming is done under agreement with stevedore companies, the price per ton is about:

3 cents for open-top boats, such as barges and lighters,
5 " " single-deck boats,
7 " " large double-deck colliers.

In mechanical plants with the ordinary car dumper, and telescopic chute at the lower end, the amount of hand trimming is estimated at about 90% of that required when boats are loaded from gravity plants. Mechanical trimmers attached to the lower end of the telescopic leg would probably require only 75% of the amount.

For estimating purposes, in connection with 200-car average daily capacity piers, when coaling to all classes of boats, the following costs per ton for trimming will represent fairly well the average prices:

(a) Gravity piers, chutes having adjustable legs...3.42 cents.
(b) Car-dumping machines with telescopic chute..3.08 "
(c) Car-dumping machine with mechanical trimmer.2.56 "

Summary.—Reasonable and fair charges per ton for the operating expenses of locomotive incline type, power incline type, and car-dumping type of plant, each working to its normal capacity of about 200 cars per day, and when yard grades are such as to permit the gravity delivery of cars from the load yard to the barney pits without engine service, are given in Table 10.

TABLE 10.—CHARGE PER TON FOR OPERATING EXPENSES FOR VARIOUS PLANTS; FULL NORMAL CAPACITY.

Items.	Locomotive incline.	Power incline.	Car-dumping machine.
	Cents.	Cents.	Cents.
Office and policing	0.38	0.38	0.38
Engine service	0.51		
Labor and fuel for machinery	...	0.49	0.84
Unloading cars	1.89	1.89	....
Total, exclusive of trimming	2.78	2.76	1.22
Trimming coal	3.42	3.42	3.08
Total, including trimming	6.20	6.18	4.30

In case the piers should work only to about 75% of their normal capacities, which is nearer actual practice, the operating charges per ton, other conditions being the same as above, will be as given in Table 11.

In cases where engine service is required for bringing the loads from the yards to the barney of barney-incline and car-dumping plants, the cost of such service should be added to that of operating either the barney-incline or car-dumping types, and, under such conditions, the operation cost per ton for the three types would be as given in Table 12.

TABLE 11.—CHARGE PER TON FOR EXPENSES WHEN OPERATING TO 75 PER CENT. OF NORMAL CAPACITY.

The charges for interest, maintenance, and depreciation also enter into the cost per ton for handling coal, and are considered in connection with and under the heading "Relative Merits of Different Classes and Types." Therefore, the operating costs alone, as contained in the foregoing tabulations, should not be considered as representing the relative economy of the different plants.

RELATIVE MERITS OF DIFFERENT CLASSES AND TYPES.

Each type of pier herein described has certain features which may give it a preponderance of merit for that particular location and those special service requirements for which it is best adapted. Therefore, the relative merits of the different types should not be judged independently of a consideration of the particular local situation and requirements which the construction of the plant will have to meet. In every case, however, where the local conditions will permit of the adoption of a gravity, mechanical, or combination type, the rela-

tive merits should be measured by the relative efficiencies for the location considered. For a proper determination of these efficiencies the following items must be examined:

(1) Discharging capacities,
(2) Ability to make simultaneous deliveries to several vessels,
(3) Relative freedom from possible breakdown which will seriously delay operation,
(4) Relative breakage of coal during delivery,
(5) Cost of plant,
(6) Interest on cost,
(7) Depreciation of plant to be taken care of by an annual fund drawing compound interest, which will amount to a sufficient sum to renew the various parts of the plant at the end of their estimated serviceability period,
(8) Cost of operation, which includes cost of handling and dumping cars, policing, office expenses, engine service, expenses for operating machinery, trimming, etc.

Items 6, 7, and 8, representing interest, depreciation, and operation, are the annual charges in connection with the plant, and, when stated in terms of cost per ton of coal output, the relative cost per ton for the different types will represent their relative economy. The plant which may have the merit of greatest economy in cost per ton of coal output, may be deficient to such an extent in regard to capacity, simultaneous delivery to several vessels, possible breakdown, and coal breakage, as to offset its apparent economy; therefore, all the eight items mentioned, and not merely apparent economy, should be fully considered when determining the relative merits of different types for a particular location.

Relative Economy.

For the purpose of determining the relative economy of a locomotive incline of Type A6, a power incline of Type A8, and a mechanical car dumper of Type B2, detailed estimates have been prepared covering:

(1) Temporary construction, namely, pile and timber work as far as practicable, that exposed in water being treated.
(2) Partly permanent construction, namely, trestle approaches, bulkheads, barney inclines, and empty return trestle for me-

chanical plants, of pile and timber construction as far as practicable; and the pier substructure and superstructure, from the bulkhead to the sea end, with the exception of barney and return trestles for mechanical plants, of steel and concrete as far as practicable.

(3) Permanent construction, namely, all parts, including approaches, to be of steel and concrete as far as practicable.

These estimates include everything except right of way, grading, and tracks, and are based on the following assumptions:

(*1*) *Local Conditions.*—Local conditions suitable for the construction of an economical design of each type, the grade in the load yards being such as to give gravity delivery of loads to the foot of the barney incline for Types A8 and B2 plants, thereby not requiring engine service for this purpose.

(*2*) *Normal Average Capacity.*—The normal average capacity of each plant to be 200 cars per day for 300 days per year, or an annual output of 2 520 000 gross tons, based on the average of 42 tons per car.

(*3*) *Dimensions.*—For locomotive and power incline types: length from bulkhead, 500 ft.; height above mean tide, 60 ft.; width at lower deck, 70 ft.; two slips, each 500 ft. long, 200 ft. wide, and 30 ft. deep.

For mechanical car dumper: pier length, 800 ft.; width, 55 ft.; only one slip, 800 ft. wide and 30 ft. deep.

(*4*) *Tracks and Grades.*—Locomotive incline: one track, 3% grade; pier deck, 2 tracks, 1% grade; empty return, one track, about 2% grade.

Power incline, Type A8: one track, 20% grade; pier deck and empty return, same as for locomotive incline.

Mechanical car dumper: barney incline; one track on 12% grade, and empty return over track on grade varying from 2 to 1 per cent.

(*5*) *Cost of Plant.*—Present average ruling prices.

(*6*) *Interest on Investment.*—5% annually.

(*7*) *Depreciation.*—The assumption is made that at the end of 25 years the conditions will have changed to such an extent as to necessitate the re-design and construction of all temporary work and machinery, and at the end of 50 years all permanent work, except dredging in slips. The charges for this depreciation are taken care of by an annual renewal fund drawing compound interest at 4 per cent.

(8) *Maintenance Charges per Annum.*—

Temporary work.—	Pier substructure and bulkheads..	5%
	Pile foundations in approaches...	5%
	Untreated framed timberwork...	10%
Permanent work.—	Steelwork	2%
	All other construction...........	1%
Machinery.—	Power incline, car dumper, scales, chutes, etc.................	10%
Dredging.—	....	1%
Operation.—	From Table 12.	

The results of the estimates are summarized in Table 13, which shows the relative economy of the different types and kinds of construction, in terms of the total cost per ton of coal output, and when based on the assumed conditions.

It will be observed that, under the assumed conditions:

(a) The mechanical car-dumper type will not only be the least expensive in first cost, but is also by far the most economical in total charges per ton of coal output;

(b) The power incline type is somewhat less expensive in first cost than the locomotive incline, and is also a little more economical in total cost per ton of coal output;

(c) That though the permanent construction, for any of the three types, will necessarily cost more than temporary or partly temporary work, it shows more economy in the total cost per ton of coal output.

For plants of greater output and greater heights than assumed, the cost per ton of coal will vary from that given in Table 13, but the relative economy of the different types will not be affected materially. If the annual output should be about 75% of that assumed, or, in other words, if the piers should work only 225 days per year instead of 300, as assumed, then the car dumper would still remain the most economical in first cost and cost per ton of coal output, but the locomotive incline, though costing a little more to construct than the power incline, would be more economical than the latter in total cost per ton of coal output.

In the foregoing comparison, although the mechanical car-dumper type, B2, is the most economical of the three types considered, under

the conditions assumed, yet it must be remembered that a single car-dumping machine can deliver coal to only one vessel at a time, and, where conditions require simultaneous delivery to several vessels, it becomes necessary to construct at least two machines, in which case economy no longer exists.

TABLE 13.—Comparative Estimates of Cost.

Type of pier.	Cost of plant.	Cost per Ton of Coal, in Cents.						
		Int.	Depr	Maint	Operation.			Total charges per ton.
					From deck.	Trim.	Total.	
Temporary Construction.								
Loco. incline, A6	$807 720	0.61	0.25	0.76	2.78	3.42	6.20	7.82
Power incline, A8	299 280	0.59	0.24	0.74	2.76	3.42	6.18	7.75
Car dumper, B2	279 640	0.55	0.22	0.66	1.22	3.08	4.30	5.73
Partly Permanent Construction.								
Loco. incline, A6	373 790	0.74	0.18	0.56	2.78	3.42	6.20	7.68
Power incline, A8	365 350	0.72	0.17	0.54	2.76	3.42	6.18	7.61
Car dumper, B2	334 640	0.66	0.16	0.52	1.22	3.08	4.30	5.64
Permanent Construction.								
Loco. incline, A6	431 400	0.86	0.12	0.37	2.78	2.42	6.20	7.55
Power incline, A8	395 980	0.79	0.13	0.41	2.76	3.42	6.18	7.51
Car dumper, B2	340 260	0.67	0.14	0.47	1.22	3.08	4.30	5.58

A plant similar to Type B4, Fig. 4, which is composed of a fixed car-dumping machine and a movable-tower car-dumping machine would be more expensive in first cost than the car dumper, Type B2, but would cost somewhat less than either the locomotive or power incline of permanent construction. The total cost per ton of coal output would be about 0.5 or 0.6 cent less than for the locomotive or power incline type, about 1.4 cents more than for the simple car dumper, B2, on the assumption that the chute is not equipped with a mechanical trimmer. Type B4 coals vessels from the tower dumper, which can be moved along the dock to the hatches of a large vessel, or to a number of barges moored to the pier, and the tower can be moved more speedily than the vessels and barges. It will require a pier length of about 500 ft., as compared with 800 ft. for the dumper alone.

Comparison of Combination with Other Classes.

Combinations of car-dumping machines with special cars and elevators or inclined planes for raising the special cars to the upper decks of the piers, such as the proposed Norfolk and Western Pier No. 4 at

Lamberts Point, the proposed Chesapeake and Ohio Pier No. 9 at Newport News, and the existing Virginian Railway pier at Sewells Point, are constructed for the purpose of meeting requirements for which the ordinary gravity types and the mechanical dumper alone are not so well adapted, and, therefore, they form a class by themselves for special work. These, of course, can be constructed in locations which also favor the ordinary gravity types or the simple car-dumping machine, but, under such conditions, there is no apparent economy in constructing a combination plant composed of a dumping machine and a gravity pier, when either one alone would serve the purpose.

Selection of a Type of Pier.

The selection of a type of gravity pier should not be made until the relative merits for the local conditions have been fully determined in the manner indicated in the preceding discussion. It is not merely a matter of adopting the plans of some pier which is in operation elsewhere, as the tendency too often prevails at present, but is a matter which involves a most thorough consideration of the dimensions and cargoes of the vessels to be loaded, the required maximum daily capacity, the probable future developments, the local conditions which affect approaches, grades, track layout, etc., and finally the preparation of a design which will meet these conditions economically.

The selection of a type of mechanical plant is also, as in the case of a gravity plant, not merely a matter of fancy or adoption of a type already built, but one of efficiency for conditions to be met, and requires the same careful study of controlling conditions and economy. As a rule, mechanical plants heretofore have not been installed where conditions are equally suitable for the construction of a gravity plant. There is a feeling, more or less unfounded, against too much machinery, and this feeling prejudices operators against such types; nevertheless, their utility is strongly indicated, and their economy is beyond doubt in certain locations, regardless of the question of individual feelings.

As indicated in the previous discussion, the combination of mechanical car dumpers with gravity piers, such as those in use and under construction in Norfolk Harbor, comprises a special class of plant adapted for service conditions which render the construction of an ordinary gravity plant or car-dumping machine impracticable.

The selection of a type evidently rests on the proper determination of its relative merits in meeting the following conditions:

(1) Free delivery of coal to all sizes and classes of boats which take coal or are likely to take coal in the port under consideration.

(2) The delivery of coal without breakage to such an extent as to be objectionable to the users,

(3) The simultaneous delivery to several vessels on one or both sides if required,

(4) Hourly capacity such as to give prompt release to vessels coaling,

(5) Economical cost per ton of coal output.

It has been shown that the car-dumping machine, Type B2, is the most economical in cost per ton of coal output, but can coal only one vessel at a time. The vessel, if a large one, must be moved so as to bring its hatches within the range of the chute, and must be taken away from the pier before another vessel can coal. These disadvantages should be weighed against its economy, and, where local conditions require the simultaneous loading of several vessels, this type is not suitable unless more than one machine is installed, and this can be done only at the sacrifice of considerable economy.

It has also been stated that the mechanical plant, Type B4, composed of a fixed car dumper and a movable-tower car dumper, though not as economical as the fixed car dumper alone, is more economical in cost per ton of coal output than either the locomotive or power incline types. It has the advantage of coaling simultaneously to two boats, one of which may be a large collier, and both boats may be kept moored to the pier while being coaled. There are no plants of this type in operation, as far as the writer knows, but it is a practicable type, and worthy of consideration.

It has also been shown that, when the yard can be constructed on such grades as to feed the coal cars to the barney pits, the barney or power incline type is slightly more economical than the locomotive incline type, but, if the local conditions are such as to require a locomotive for delivering the coal cars from the yard to the barney, then this type is not as economical as the locomotive incline type, but it has

an advantage in many locations where the space back of the bulkhead is contracted.

As a general proposition, where the location will permit of its construction, and vessels coaling cars are of moderate height, and where the capacities are between 20 and 30 cars per hour, the locomotive incline type has proved more satisfactory than any of the others, on account of the simplicity of its construction and freedom from heavy or complicated machinery.

Proper Design and Construction.

After having determined which type of pier has a preponderance of merit for the local situation and the conditions under which it is to be operated, it should be designed and constructed in such a manner as to obtain the greatest possible efficiency and economy consistent with the type selected.

The best results cannot be obtained by copying the plans of some similar pier, because most piers thus far designed have defects which impair their efficiency, and though in some cases the defects of design have been remedied after the piers have been placed in service, the original plans in all probability remain unchanged.

The proper determination of heights, lengths, widths, number of tracks, grades, switchbacks, construction of bins or pockets and chutes, etc., though usually considered as details of the design, are just as essential for the effective operation of the plant as the proper design of the carrying parts is for the safety of the structure.

All the so-called details have been rather fully discussed herein, and therefore a repetition is not necessary. The salient points, however, may be briefly summarized, as follows:

(1) The height of a gravity pier above mean tide should be from 33 to 43 ft. above the highest hatches of vessels coaling at the port, and will depend on the type of chute and the storage capacity of the bins.

(2) The length from the bulkhead to the sea end of a gravity pier should be not less than about 700 ft., in order to accommodate Government colliers and the probable future steamers of the New England Coal and Coke Company.

(3) The least practicable width for gravity pier coaling from two sides is about 70 ft.

(4) Grades on locomotive inclines should preferably not exceed 3%; on barney inclines to gravity piers, 18%; on barney inclines to mechanical plants, 12%; and on empty return tracks, 2 per cent. Grades for gravity movement of loads should preferably be not less than from 0.8 to 1.25%, depending on southern or northern location. All changes in grades should have easements.

(5) Switchbacks are preferable to pivot tables, and should be constructed so that grades may be readily adjusted to meet varying conditions of weather and temperature.

(6) Tops of pockets or bins should have a length of at least 12 ft. and a width of at least 9 ft., for receiving coal from either a hopper or gondola car. The slopes should be not less than 40° from the horizontal, and preferably 45°, with leads to the chute designed so that they will not form a wedge at the pocket outlet. A pocket free from sharp corners, and constructed on lines of curves rather than of angles will permit the coal to flow more freely.

(7) Metal chutes with adjustable legs at the pier connection, or a similar type, are superior to the simple hinged chute. Where electric power is available, and the pier has a large output to cargoes of various sizes, the adjustments should be controlled by motors. For a free flow of coal, the inclination of the chute from the horizontal should be about 40° for bituminous coal. Chutes with telescopic legs at the discharging end cause less breakage of coal than other types, and require less trimming.

The question as to whether the construction shall be temporary, partly permanent, or wholly permanent is one of policy, to a large extent. In most of the piers, both substructures and superstructures are of temporary construction, and all gravity piers thus far built are of temporary construction back of the bulkhead. Temporary work is the least expensive in first cost, but is less economical than either partly permanent or wholly permanent construction, as the total cost per ton of coal output will be the highest when interest, depreciation, and maintenance are taken into consideration.

A pier should be properly designed, not only to meet requirements as to normal and maximum hourly output, but also the very probable general increase in cargoes, and the capacity and weight of coal cars. Mechanical car dumpers are now designed for handling coal cars of 100 tons capacity. The construction, therefore, no matter whether temporary or permanent, should by all means be substantial and simple in character, and, in most cases where piers will probably meet conditions for a period of 25 years, it will be true economy to construct all work from the bulkhead to the sea end, for both substructure and superstructure, in a permanent manner, even if the approach trestlework and empty return be of temporary construction.

Paper No. 1292

MODERN PIER CONSTRUCTION IN NEW YORK HARBOR.*

By Charles W. Staniford, M. Am. Soc. C. E.

With Discussion by Messrs. E. G. Walker, Edwin J. Beugler, Harrison S. Taft, F. R. Harris, J. P. Snow, Tyrrell B. Shertzer, C. H. Stengel, L. D. Cornish, L. J. Le Conte, Chandler Davis, R. T. Betts, and Charles W. Staniford.

Introduction.

The present general port activity and agitation for a modernization and expansion of the dock and wharfage system in New York City indicate that at last the community at large seems to realize the necessity of keeping its producing plant, the harbor, up to date and at the top notch of efficiency.

It has been said that "all roads lead to New York." Never was this more true than to-day. New York in 1913 is the world's greatest seaport, its greatest factory, and its largest department store.

There can be no question that New York City's supremacy as a manufacturing and distributing center is due to wise adaptation of its magnificent harbor. The phenomenal increase in the size of vessels, necessitating longer docks, and the great and constant increase in tonnage entering the harbor, both demand determined action in port development.

New York is approximately equidistant from the ports of Northern Europe and South America. Therefore, it will undoubtedly receive additional impetus in its commerce and shipping on the completion of

* Paper presented at the meeting of September 3d, 1913.

the Panama Canal. Further, on the completion of the New York State Barge Canal, it will have a direct all-water route to the Great Lakes and the North Middle States and Canada, and the Cape Cod Canal will tap New England commerce.

Far-sighted public men foresee that New York is destined to become the world power in commerce and industry, and realize that it must prepare for the future intelligently and on broad lines, permitting gradual expansion as required by commercial necessity.

Growth and Development of the Harbor.

In this period of harbor activity, it will be of interest to both the public and the engineer to describe the gradual development of the harbor, as such development was first systematically undertaken by the City, when, in 1870, the Department of Docks was organized for this purpose, and to show the types of pier construction evolved.

In considering the history of dock development in the City of New York, through the instrumentality of the Department of Docks, it must be borne in mind that, in its early days, the Department was greatly handicapped in its progress by the fact that the City actually owned only a very small portion of its great water-front, most of it having passed, by successive water grants, into the control of private interests.

It had been the policy of the New York State Government, prior to the organization of the Department of Docks, to give to corporate interests or private persons grants of land under water in that portion of the present City outside of Manhattan, the object and hope in making such grants being that such cession of land under water would be a sufficient incentive for the investment of private capital in the development of the port.

The hopes of the State and City were fully realized; in fact, they were so generally fulfilled that when the port authority, created by the Legislature in establishing the Department of Docks for the purpose of intelligent development under municipal control, began to consider the expansion of wharfage facilities to meet the demands of the growing commerce, it found but little actual water-front in possession or under control of the City.

That the early City authorities used wisdom and foresight in their work of providing for proper expansion of the harbor is shown by the fact that, through their sagacity and good judgment, the number of

piers in the harbor, owned by the municipality of New York, grew from 107 in 1868, valued at $20 000 000, to 232 in 1913, valued at $100 000 000 or more.

There has accrued, therefore, to the City, a return on its investment in this development of the dock system, a large sum of money in increased valuation and annual rent receipts, the latter aggregating in round figures about $4 000 000 per annum, the interest at 4% on a capital of $100 000 000.

It will be seen that, at the outset, the Department of Docks, concluded that proper growth and expansion of the harbor under municipal control depended on the acquisition and control of water-front property; and since the organization of the Department of Docks, this has been the policy followed by the City.

When, in 1870, the municipal authorities undertook the burden of increasing the wharfage facilities of the harbor, and of procuring funds for this purpose, it became necessary, as a basis for their work, to determine on some economic form or type of construction, both in regard to the pier structure proper and also the general location with respect to the available shore front, whereby the maximum wharfage accommodation could be developed without excessive or prohibitory cost.

The limited funds available and the small extent of water-front lands under the actual control of the City called for the greatest economy in space, the land requiring intense development in order to obtain the greatest possible extent of wharfage.

Bond issues to be applied to the development of wharfage had to show the same return on the investment, when executed by the City authorities, as if these finances were handled by private parties or corporate interests. Therefore, what might be termed the "principle of economy in expenditure of land and funds" was, of necessity, followed, and this principle was generally adopted by private interests as well, the consequent intensive use of the water-front resulting in the adoption of a uniform method of development by a definite system, namely, parallel piers generally at right angles to the general direction of the water-front, with intervening slips wide enough to accommodate vessels of the type intended to berth at the piers.

This parallel system of economically constructed piers, with its resulting economy in space occupied and capital expended, was undoubtedly one of the greatest factors in stimulating the development

and expansion of the wharfage facilities in the harbor, and in keeping them abreast of the constant increase in shipping and commerce. It has also created by far the greatest wharfage space of any harbor in the world.

The wooden pier, consisting of a timber deck and floor system supported by timber piles, became the adopted type. It was cheap, durable, and readily adaptable to all classes of shipping. One of the most important characteristics of piers of this type is the ease and economy with which it may be removed entirely, reconstructed wholly or in part, or expanded, at a low cost, to meet the increasing needs of commerce and shipping. A dock or system of docks sufficient to accommodate the shipping at the time it was built, might be found to be inadequate and obsolete within a comparatively short term of years, a complete re-arrangement being then necessary.

With timber structures, this transformation or reconstruction is a simple, rapid, and economical undertaking; it is difficult and costly with structures of stone, concrete, steel, etc. The use of concrete piles, reinforced concrete substructures or similar forms of construction, therefore, would not only have resulted in high first cost of construction, but the difficulty and expense incidental to the periodical removal, reconstruction, or expansion of dock structures of this type, as necessitated from time to time by the growth of shipping, would have rendered harbor construction work, as a revenue-producing municipal investment, practically impossible, and, consequently, would have greatly retarded the development of the harbor.

Types of Pier Construction.

The United States Government, by virtue of its power to control all navigable waterways in the country, established along the entire waterfront or shore line of New York Harbor two lines: one the bulkhead line, which limits the extent outshore of the solid filling or reclaimed land under water; the other, the pierhead line, which determines the limit to which piers may extend beyond the bulkhead line. These piers must be of such construction that the free flow of the tidal water shall remain uninterrupted by the supporting columns. This construction, being a condition wisely insisted on by the Government to preserve tidal conditions and currents, governs, to a great extent, the handling of vessels, particularly of large ones, and affects the sanitation of the City,

in that it prevents the accumulation of sewage and refuse which would occur in closed slips. With open slips, such matter is carried away by, and disseminated in, the tidal flow. All pier construction is limited to the area included between the bulkhead and pierhead lines.

The pier which meets these requirements, and was adopted by the City in its early history as the type of structure for berthing vessels (and also adopted by all private and corporate interests), is a wooden structure throughout, consisting of a deck resting on piles driven into the mud or hard bottom. The physical features of the harbor, the geological formation of the bottom, and the condition of the water, fortunately permit the adoption of this type of construction, which, in many other parts of the world, is not adaptable because the life of the timber itself in the water would not be permanent or fairly long-lived. Wood-boring animals, the teredo, limnoria, etc., are very little in evidence, and, therefore, wooden piles are practically permanent below the water-line in almost all parts of New York Harbor.

The prominent objectionable feature to wooden pier construction is the expense necessitated by the constant repairs of the deck sheathing and the continuous wear and tear of the fender system extending along the sides and outer ends of the piers. As to the remainder of the structure, piles, floor system, etc., its maintenance and repair is very economical and consists generally in the replacement, from time to time, here and there, of decayed portions of the timber above mean low water only, at inconsiderable expense.

Until seven or eight years ago, the piers were generally built with decks of yellow pine, 4 in. thick, laid on a system of yellow pine floor structure of rangers and stringers. This deck plank in turn was covered with a second layer of either 3- or 4-in. plank sheathing, laid diagonally or at right angles to the deck proper, to form a wearing surface for the traffic.

Constant repairs and renewal of this deck sheathing, caused by the wear and tear of team traffic, is augmented in great measure by the moisture, horse urine, etc., which saturates the wood and eventually finds its way to the underlying deck and rangers. This forms the greatest item incident to the expense of pier maintenance, the average life of the sheathing for most busy piers being about 6 years, or requiring a 17% renewal annually. As the cost of the deck sheathing is generally about 12% of the total cost of a pier, it will be seen that these

sheathing repairs would aggregate 2% per annum of the cost of the entire structure.

New Pier Construction Practice.

Notwithstanding the necessity for constant repairs to the deck sheathing of the wooden pier, the parts of the remainder of the structure —rangers, caps, stringers, piles, and bracing—give excellent service. Maintenance is economical, the average life of the structure above mean low water line being from 20 to 25 years, the repairs aggregating an entire renewal above low water in that period of time. As the life of the piles supporting the structure is practically permanent when submerged below the water, the entire structure can be rebuilt after this period and made practically new by "bench capping" such piles as may be decayed above the water line and renewing the stringers, caps, deck, and sheathing; in other words, the pier structure proper, after a life of 25 years, is readily susceptible of renewal above the water line, the supporting piles below that line being to all intents and purposes permanent.

It will be readily seen that the life of the wooden pier structure would be prolonged still further, and the cost of maintenance and repairs reduced, by the elimination of the objectionable wooden deck sheathing and its replacement by some form of deck impervious to moisture and resisting the wear and tear of traffic.

It was with the object of eliminating this large repair expense incidental to the maintenance of the sheathing, and reducing maintenance cost generally, that the Engineering Bureau of the Department of Docks and Ferries, under the direction of J. A. Bensel, Past-President, Am. Soc. C. E., then Commissioner of Docks, about seven years ago, began a serious investigation and study of the problem of producing a permanent deck surface supported by timber piles, assumed as permanent below the water line.

This study has resulted in the entire elimination of the old style of wooden deck in new structures, and the production of a new type consisting of reinforced concrete laid directly on the transverse cap system of the wooden pier substructure. This concrete is laid in slabs, spanning the pile bents practically as simple beams.

This new type of deck eliminates not only the 4-in. deck sheathing, but also the 4-in. deck proper and the underlying 12 by 12-in. yellow pine ranger system longitudinally of the pier on top of the transverse cap system, further increasing the life of the substructure.

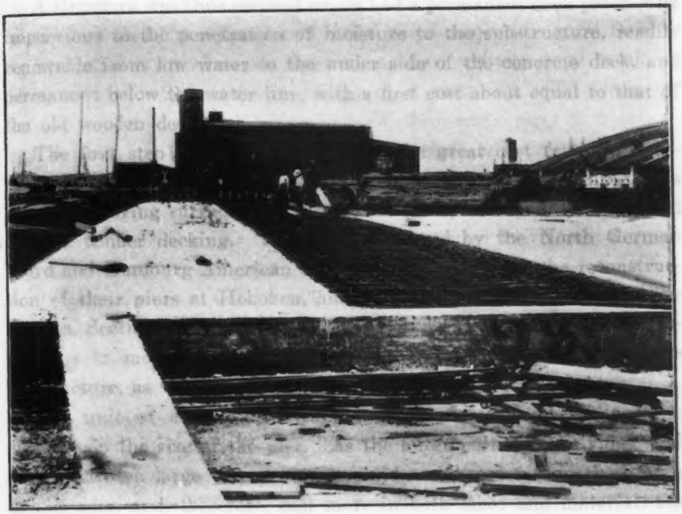

FIG. 1.—STRIP OF CONCRETE DECK AND STEEL REINFORCEMENT.

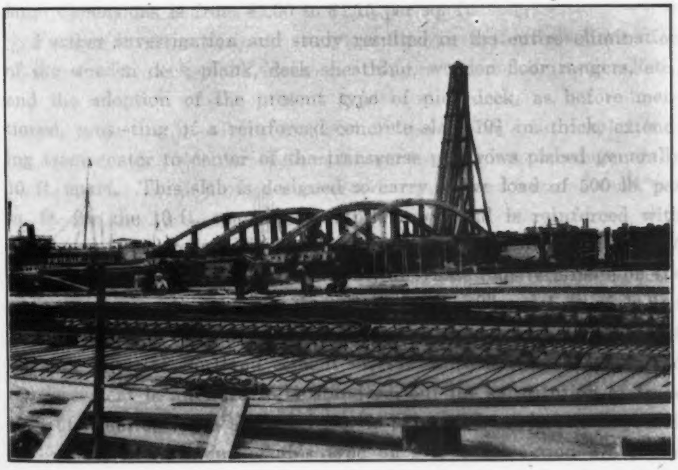

FIG. 2.—TENSION REINFORCEMENT AND TEMPLATES FOR HOLDING IN POSITION.

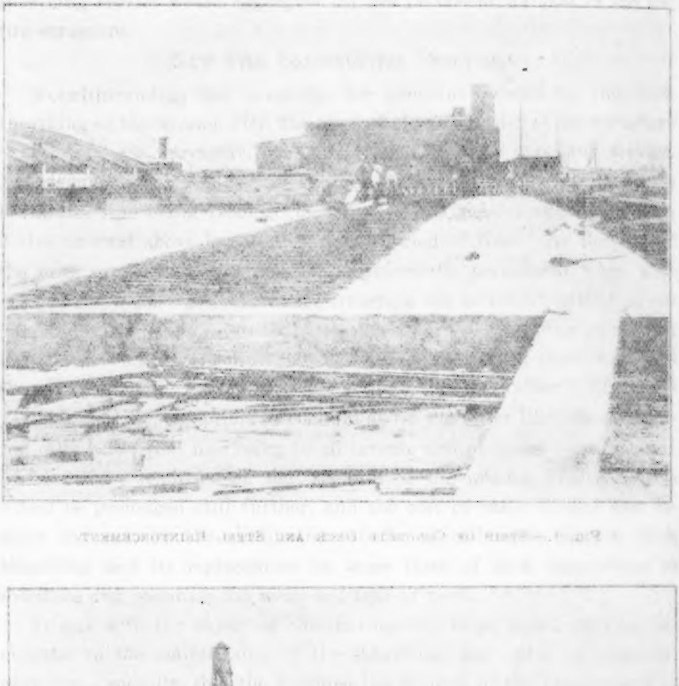

FIG. 1.—SPAN OF CONCRETE DECK AND STEEL REINFORCEMENT.

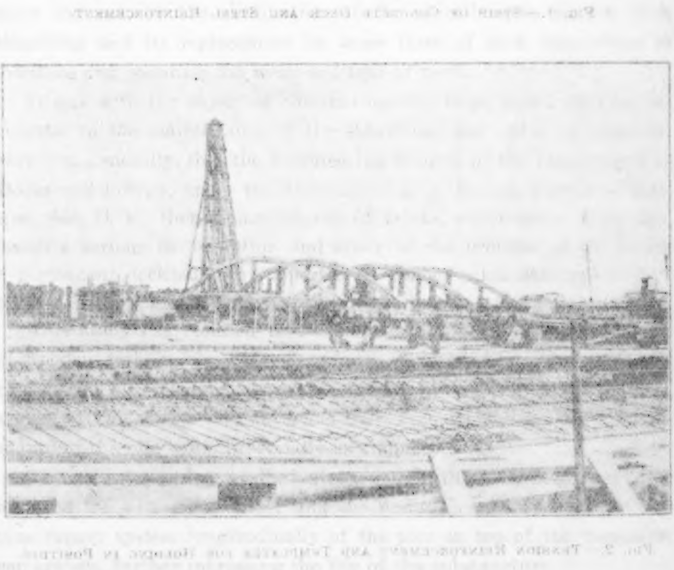

FIG. 2.—TRUSSED REINFORCEMENT AND TEMPLATES FOR HOLDING IN POSITION.

A structure was thus evolved which had a permanent deck practically impervious to the penetration of moisture to the substructure, readily renewable from low water to the under side of the concrete deck, and permanent below the water line, with a first cost about equal to that of the old wooden deck pier.

The first step in the elimination of the great cost factor, the renewal of the deck sheathing, was the replacing of this sheathing by a concrete wearing surface, from 4 to 6 in. thick, laid directly on the old type of timber decking. This type was used by the North German Lloyd and Hamburg American Steamship Companies in the reconstruction of their piers at Hoboken, and by the City of New York in the Chelsea Section piers, the result being a deck surface which is impervious to moisture and urine, and, therefore, a protection to the substructure, as well as a saving in maintenance.

The unit of cost of construction of a pier depends in a large measure on the size of the pier. As the outer portions, the sides, and outer end of a large pier are more rigid and heavier than those of a smaller pier, and, therefore, cost more in both labor and material, the relative cost per square foot of a short pier is considerably larger than that of a long one. The average cost of the old wooden deck pier of large dimensions is from $1.00 to $1.15 per sq. ft.

Further investigation and study resulted in the entire elimination of the wooden deck plank, deck sheathing, wooden floor rangers, etc., and the adoption of the present type of pier deck, as before mentioned, consisting of a reinforced concrete slab, 10½ in. thick, extending from center to center of the transverse pile rows placed generally 10 ft. apart. This slab is designed to carry a live load of 500 lb. per sq. ft. for the 10-ft. span between pile rows, and is reinforced with ⅝-in. square steel rods. The latter run longitudinally of the pier, are 6 in. apart, and are staggered so that only alternate rods terminate on the same pile row, with ⅜ by ⅜-in. separating rods. The slab is of 1:2:4 Portland cement concrete, with ¾-in. broken stone, the upper ½ in. of the slab being of Portland cement mortar finished smooth. This rod reinforcement is intended to be standard, but the substitution of trade sizes of equal strength and efficiency is permitted, subject to approval.

Definite illustrations of this type of pier construction are found in the two new piers recently completed by the Department of Docks and Ferries at the Gowanus Section, South Brooklyn, one at the foot of

31st Street, 1 475 ft. long, and the second at the foot of 33d Street, 1 616 ft. long, each pier being 150 ft. wide. These piers are among the finest in the harbor, and are probably the largest of their type in the world. The unit cost is practically the same as that of the old wooden deck type. The decks have a crown of about 8 in., in order to shed the water. The inshore end of the concrete deck rests on the bulkhead wall, but is not attached thereto, a horizontal plane joint allowing the deck to slide on the wall as it expands or contracts on account of changes of temperature.

Twenty-six piers with concrete decks have been built by the Department during the past 7 years. The earlier type, as exemplified by the Chelsea Section piers, consists of a 6-in. concrete deck surface reinforced with expanded metal and laid directly on the deck planking. The next type produced omitted the deck plank, and is represented by eight piers with decks consisting of a concrete slab, 6½ in. thick, reinforced with expanded metal, the slab spanning yellow pine rangers running longitudinally of the piers and generally about 6 ft. apart.

The final type evolved, omitting the timber floor system entirely, and placing a concrete slab reinforced with longitudinal steel rods directly on the timber-capped transverse pile rows, is represented by eight piers, the most important examples being those at the foot of 31st and 33d Streets, South Brooklyn, and the Municipal Pier at Stapleton, Staten Island.

All these piers have been built where the condition of the river bottom underlying them was such that no settlement could occur, and they have behaved admirably. No repairs have been necessary, except to the fender system, and none are anticipated for many years to come, excepting the renewal here and there of an imperfect pile, where rot may appear above the water line. Such renewals can be made at a minimum of cost—a few dollars per pile—by bench-capping, without any interference whatever with the integrity of the reinforced deck itself.

Column Foundations.

For single-story sheds, where additional bearing strength is required in the new concrete deck pier for shed column or superstructure support, the question has been treated in general in the same manner

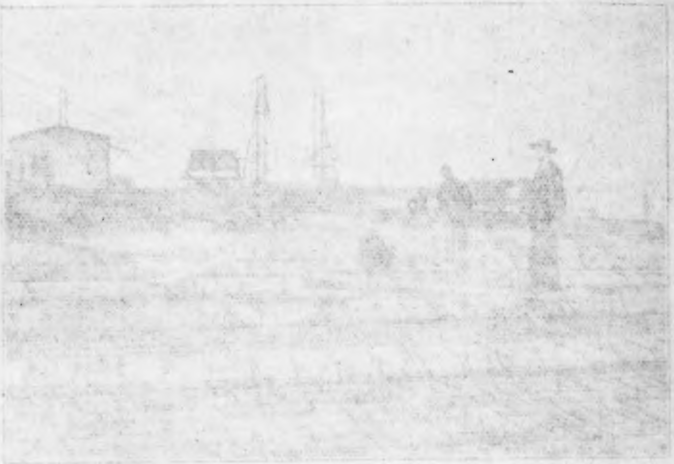
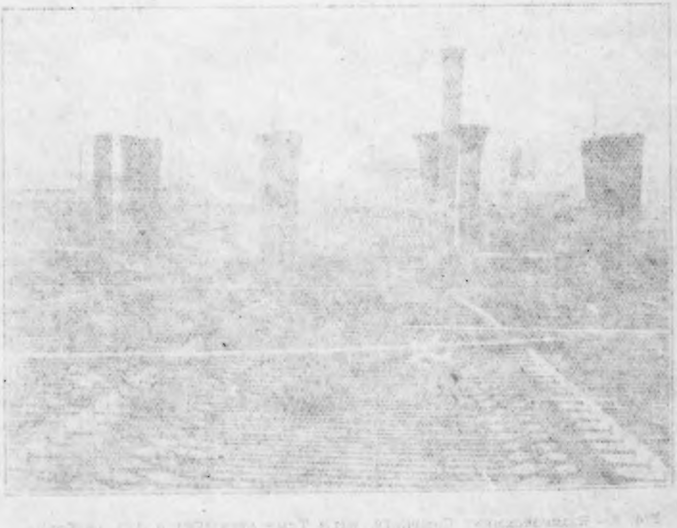
Fig. 4.—Reinforcement Complete, with Templates Which Act as Forms for the Alternate Strips of Concrete Deck.





as in other parts of the structure, that is, by adding the necessary number of piles to carry the load concentrations, assuming the piles to be permanent below low water and easily renewable above that plane.

Where heavier concentrations occur, as, for example, in double-deck or two-story sheds, the piles are cut off at or near low water and covered with a timber grillage; built on this grillage are reinforced concrete pedestals, extending to the deck level, to carry the shed columns.

Railroad tracks, being a requirement on the South Brooklyn piers previously described, are carried on four lines of 15-in. steel I-beams, placed on the transverse clamp system of the pile rows and extending from the inshore end of the pier sheds to within 60 ft. of the outshore shed wall. The beams rest on steel saddles placed on the clamps, and are entirely encased in concrete.

TABLE 1.—COST OF CONSTRUCTION, MAINTENANCE AND REPAIRS.

Average Cost of Construction of Wooden Deck Piers, \$1.00 to \$1.15 per Sq. Ft.

REPAIR COSTS OF WOODEN DECK PIER.

Description.	Percentage of total original cost.	Renewal required.	Remarks.
Sheathing	12	Every 6 years.	
Backing log	1.8	Every 8 years	
Fender chocks, including vertical sheathing	4	Every 10 years.	
Fender piles	4.7	Every 12 years.	
Decking	11.3	Every 15 years.	
Bracing	7.1	50% in every 20 years.	
Rangers and caps	24.4	50% in every 20 years.	
Piles	34.7	33⅓% every 20 years.	Above M. L. W. only.

CONCRETE DECK PIER.

Cost of construction, 31st Street Pier,
South Brooklyn, no asphalt surface, \$0.87 per sq. ft.

Cost of construction, 33d Street Pier,
South Brooklyn, with asphalt surface, 0.97 " " "

Economy being a prime factor in its construction, it was decided to try out the concrete deck surface for wear and tear of heavy team traffic, and the earlier decks, therefore, were finished with a smooth mortar surface to receive this traffic. Two years of experimenting on these lines, determined the fact that though the concrete surface was

admirably adapted to light traffic, cargo handling by hand or motor trucks, etc., it could not stand the concentration of heavy team traffic confined within narrow lanes located generally in the center of the pier. The grinding and turning of heavily laden trucks inside these narrow lanes or zones gradually caused surface rupture of the top coat of mortar. It was decided, therefore, to place an asphalt wearing surface on the deck, and this has proven very effective.

The piers at the foot of 31st and 33d Streets, South Brooklyn, have been in service for about 3 years. No signs of cracking or other imperfections have appeared, and the piers as a whole are a complete success.

Repairs.

For the modern type of concrete deck pier, the cost of maintaining the fender system is about the same as that for the wooden pier; deck sheathing repairs are practically eliminated, except such minor asphalt patching as may be required, and can be considered negligible in a good asphalt deck under cover; the deck plank is eliminated; the life of the ranger and cap system is prolonged by the protection from moisture given by the impervious concrete deck, and the cost of maintenance and repairs, therefore, is reduced to a minimum.

Conclusions.

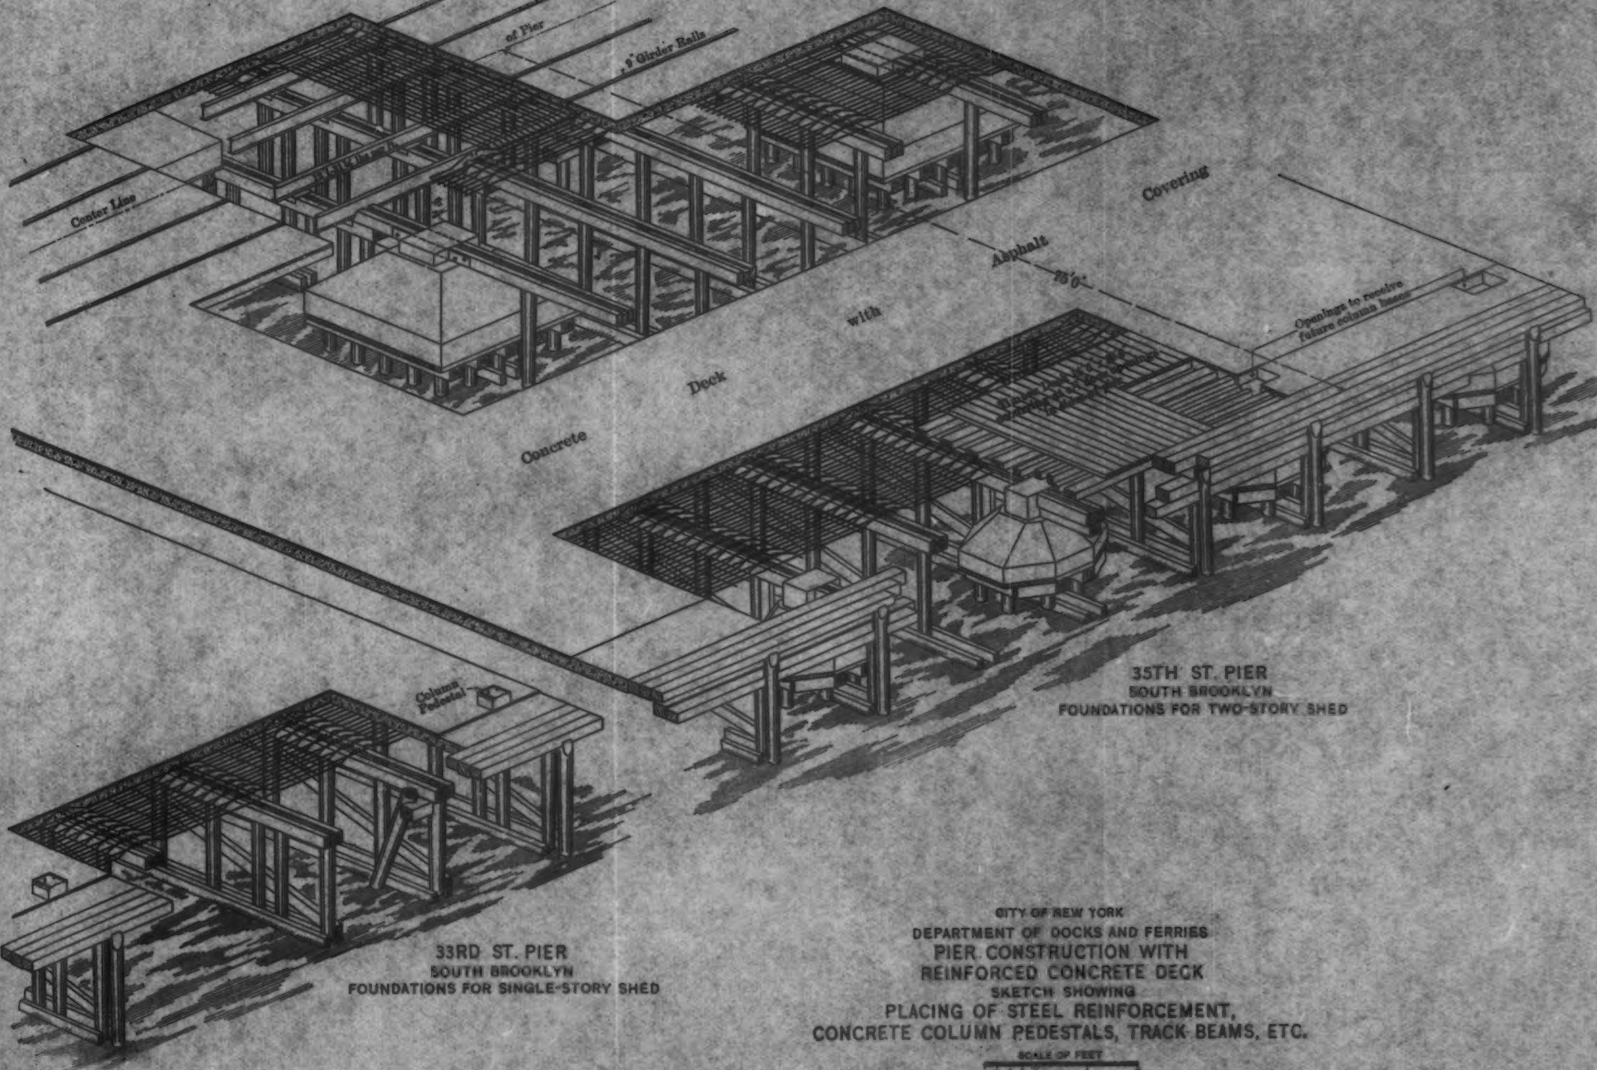
From the foregoing it will be observed that the problem which confronted the Department was the elimination of the timber deck and deck-supporting structure of the wooden pier, by the substitution therefor of some permanent form of construction meeting the following requirements:

(*a*) Economy in cost of construction and maintenance, the unit cost to be such as to produce or make possible a remunerative return on the capital invested.

(*b*) The construction to be of such character as to be readily extended, reconstructed, re-modeled, or, if necessary, entirely removed, as more intensive development of the area occupied by the pier or system of piers might be made necessary by the growth of commerce and shipping.

From what has been stated the following conclusions may be deduced:

PLATE VIII.
TRANS. AM. SOC. CIV. ENGRS.
VOL. LXXVII, No. 1292.
STANIFORD ON
PIER CONSTRUCTION
IN NEW YORK HARBOR.



CITY OF NEW YORK
DEPARTMENT OF DOCKS AND FERRIES
PIER CONSTRUCTION WITH
REINFORCED CONCRETE DECK
SKETCH SHOWING
PLACING OF STEEL REINFORCEMENT,
CONCRETE COLUMN PEDESTALS, TRACK BEAMS, ETC.

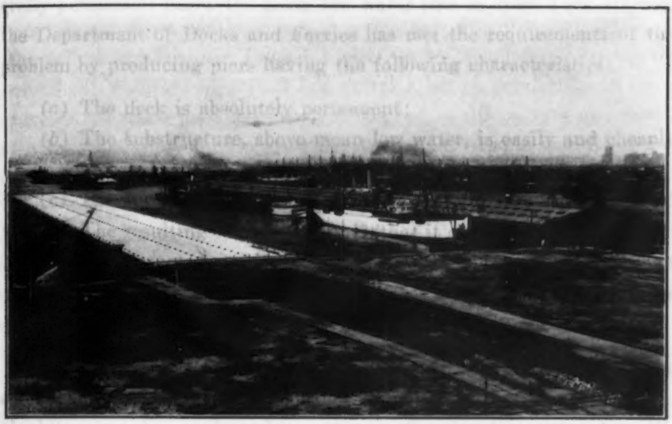


FIG. 5.—TWO PIERS WITH REINFORCED CONCRETE DECK, EACH 150 FT. WIDE. ONE 1 475 AND THE OTHER 1 616 FT. LONG.

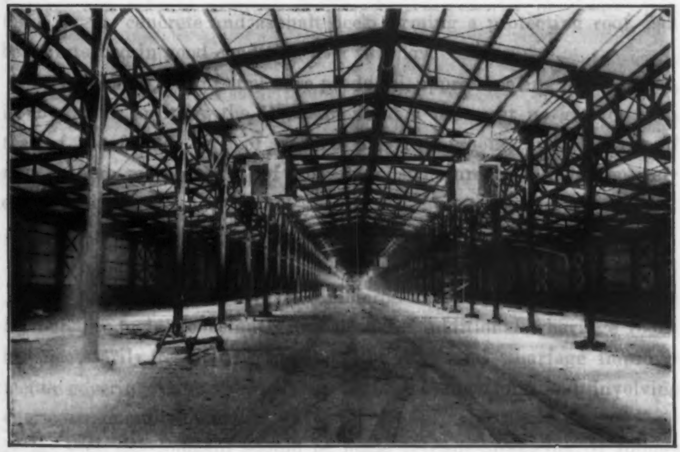

FIG. 6.—INTERIOR VIEW OF SHED ON PIER, 150 FT. WIDE AND 1 616 FT. LONG, SHOWING CONCRETE DECK AND TRACK STRINGERS, READY FOR RAILS.

First. Admitting that timber piles and foundation work are generally permanent below the mean low water line in New York Harbor, the Department of Docks and Ferries has met the requirements of the problem by producing piers having the following characteristics:

(*a*) The deck is absolutely permanent;

(*b*) The substructure, above mean low water, is easily and cheaply repaired and maintained;

(*c*) The supporting part, below the water line, is permanent; and

(*d*) The resulting structure is such that it can be readily extended, reconstructed, or, if necessary, entirely removed at a cost not prohibitive, as would be the case, for example, with most types of reinforced concrete deck-supporting structures.

Second. That the Department has produced permanent parts in the structures where these are essential. No attempt was made to obtain absolute permanency above low water, in the structure supporting the deck, for the reason that,

Third. This portion of the structure, the caps, piles, braces, etc., protected as they are from saturation by urine and other objectionable fluids by the concrete and asphalt deck forming a protecting roof, can be maintained in good condition at a very low cost.

Fourth. The type of structure produced, approximating permanency, is now being built by the Department at a first cost no greater than that of the former type of wooden pier throughout, and the cost of repairs and maintenance of the deck structure is almost entirely eliminated.

General Remarks.

The phenomenal growth of commerce and shipping in New York Harbor, producing constantly the need for additional wharfage room, has necessarily resulted in projects for dock and wharfage improvements covering extensive portions of the water-front and involving enormous amounts of money.

As such development should be made revenue-producing, it follows that a cheap type of pier construction, low in first cost, long of life, and economical to maintain, is one of the fundamental factors in determining the extent of the improvements undertaken not only by the City

of New York, but by private interests as well. This does not necessarily follow when smaller cities are considered.

Compared with the vast amount of money necessary for the comprehensive development of the port, the sums required for similar purposes by other ports on the Atlantic and Pacific seaboards of the United States are very small, in fact, in many cases, comparatively insignificant. Harbor improvements at these ports are generally confined to a limited area or extent of water-front, and consist usually of a few piers or bulkheads. Their aggregate cost is such that, even if not revenue-producing, the investment is often well within the financial capacity of the municipality and wisely undertaken by reason of its effect in stimulating existing trade and attracting new shipping business, producing what might be called "indirect revenue." This has often been the incentive in inaugurating harbor improvements at these minor ports, and it has resulted, in some instances, in absolutely permanent structures at such great expense that remunerative return on the capital invested is highly improbable, if not impossible; in other words, the benefits derived are being consummated at too great a cost, even when considered from the point of view of "indirect revenue."

Notwithstanding the many desirable features of this new type of pier construction, it has not been generally adopted, though many inquiries and requests for plans and descriptions of the type and method of construction have been received and replies made thereto, pointing out its proven economy in first cost, repairs, and maintenance. New York Harbor, however, presents a number of examples of similar types of concrete deck piers adopted by private interests, notable among which are: The reinforced concrete deck pier built by the Central Railroad of New Jersey at Communipaw, N. J., 892 ft. long and 131 ft. wide, used for railroad freight, tracks being laid on the pier deck; the pier under construction by the United States Lighthouse Board in the Reservation at St. George, Staten Island; and in two piers now under construction at the Brooklyn Navy Yard. The design of the latter, particularly, presents an admirable combination of reinforced concrete construction, surmounting the wooden pile and grillage supporting foundations near low water, resulting in a practically permanent pier at an economical first cost.

When reinforced concrete piers have been built at other ports along the coast, the attempt at absolute permanency, as stated above, has gen-

erally resulted in prohibitive first cost, when considered as a business proposition requiring interest on the capital invested.

Where the life of the wooden structure below the water is not endangered by wood-borers—in other words, where it can be considered as permanent—the difference in cost between an elaborate reinforced concrete pile and deck-supporting structure throughout, and a structure of the type herein described, represents practically that amount of money uselessly wasted.

Further, it is an open question whether the rigidity of a reinforced concrete structure throughout would not be a serious cause of deterioration in such structures, particularly below the water line. The shearing action of the impact of a large ocean-going steamship with a pier of this rigid type might cause a dangerous condition in the entire structure difficult to repair or overcome; even shocks tending to break the concrete surfaces of piles and substructure would admit sea water with its consequent destructive chemical action and freezing in cold weather.

On the other hand, the timber and pile substructure, with its flexibility and elasticity, acts, to a considerable extent, as a shock absorber, dissipating the effect on both the vessel and the pier, consequent on the impact of the collision or more or less violent contact with the pier, sometimes occurring when warping vessels into their berths.

The personnel of the Department of Docks and Ferries, as at present constituted, is as follows: Mr. R. A. C. Smith, Commissioner; Bureau of Engineering: The writer, Chief Engineer; S. W. Hoag, Jr., M. Am. Soc. C. E., Deputy Chief Engineer; and R. T. Betts, M. Am. Soc. C. E., Assistant Engineer, in charge of design.

DISCUSSION

Mr. Walker. E. G. WALKER, JUN. AM. SOC. C. E. (by letter).—The Engineering Staff of the Department of Docks and Ferries of New York City has evolved a novel and effective type of pier, without introducing any drastic departures from generally accepted methods of construction. Composite structures in which reinforced concrete is used are common, but a reinforced concrete decking on a timber pier, as detailed in the paper, is less common, and, in many cases, would need special justification by reason of the great difference which generally exists between the life of a concrete work and that of a timber structure set in water. In New York Harbor, however, there is a special combination of conditions, which, as a rule, does not occur elsewhere, and makes the composite piers described an admirable solution of the problem of providing wharfage space economically.

The figures in Table 1 show an appreciable saving in first cost by the adoption of the new construction, but no direct figures are given as to the relative maintenance costs. Inasmuch as reduction of the latter cost is often of greater importance than a small saving on first cost, the writer has endeavored to arrive at some relative figures from the data in the paper. From Table 1 he has obtained by deduction the figures in Table 2.

The author claims that, with the concrete and asphalt decking, repairs to sheathing and decking are practically eliminated, and that repairs to rangers and caps are reduced considerably. This gives the approximate figures in Table 3.

This total is only about 46% of the total annual cost of maintenance of the timber-decked piers, considering only equal capital expenditure. Inasmuch as the average cost per square foot for timber-decked piers is \$1.07, and for concrete-decked, \$0.97, it follows that the average annual costs per square foot for maintenance are:

For wooden deck piers.........\$1.07 $\times$ 0.0515 = \$0.055
For concrete deck piers........\$0.97 $\times$ 0.0234 = \$0.023,

showing a reduction of 58% by the use of concrete.

If this deduction is correct, it is obvious that a very great economy may be effected when large areas of timber piers have to be dealt with.

One feature of the composite pier construction has been omitted by the author, apparently owing to the fact that sufficient time has not yet elapsed to enable the requisite experience to be obtained. The necessity for fairly frequent reconstruction and removal of piers, or portions of them, is emphasized in the paper, but it is evident that the demolition of a reinforced concrete decking, though probably less troublesome than the removal of reinforced concrete piles and bracing, is still a considerably heavier and more expensive undertaking than

Mr. Walker.

the removal of timber decking. In cases where there is much chance of alteration of arrangements this might reduce very considerably the economy obtained by the use of composite piers. The writer would be glad to learn whether there are any data on this subject.

TABLE 2.—REPAIR COSTS OF WOODEN DECK PIERS.

Description.	Percentage of total original cost.	Number of years required for complete renewal.	Percentage of average annual cost of renewal.
Sheathing	12	6	2.00
Backing log	1.8	8	0.23
Fender chocks, including vertical sheathing	4	10	0.40
Fender piles	4.7	12	0.40
Decking	11.3	15	0.75
Bracing	7.1	40	0.18
Rangers and caps	24.4	40	0.61
Piles	34.7	60	0.58
Total annual cost of renewals, averaged over 60 years			5.15

TABLE 3.—REPAIR COSTS OF CONCRETE DECK PIERS.

Description.	Percentage of average annual cost of renewal.
Sheathing and decking	0.05 (say)
Backing log	0.23
Fender chocks, etc	0.40
Fender piles	0.40
Bracing	0.18
Rangers and caps	0.50 (say)
Piles	0.58
Total annual cost of renewals, averaged over 60 years	2.34

Possibly additional economy might be obtained by reducing the deterioration of the piles. In Table 3 it will be seen that renewals to piles form the largest item, namely, 0.58% per annum. It may be presumed that, as the destructive agency of marine boring insects is absent, the main deterioration of the piles is the decay which takes place on the alternately wet and dry surfaces between the extremes of tidal range. It might be worth considering whether a saving could not be effected by casing old piles in concrete for a sufficient length to prevent further decay. A casing of moulded concrete slabs. suitably reinforced and filled with concrete, can be fitted around a pile at very little cost, and is sufficient to retard almost indefinitely its deterioration. This method has proved effective in a number of instances.

Mr. Beugler.

EDWIN J. BEUGLER, M. AM. SOC. C. E. (by letter).—As literature on pier construction at American ports is somewhat limited, and engineers are frequently in the dark as to practice at the larger shipping centers, this paper will be appreciated by those having to do with the construction or maintenance of wharves and piers. American engineers have been criticized frequently for the adoption of what appears to be a temporary expedient in the way of shipping facilities, even at the larger ports. The analysis given in this paper will explain many of the questions as to why the particular type of pier construction commonly used in New York Harbor was adopted.

New York City is unique in regard to local conditions which favor the use of timber in the construction of piers. Though the cost of timber has been advancing from year to year, and will continue to do so until the figure reaches a point where other materials will have to be used from an economic standpoint, the substitution of concrete for the deck of the pier has enabled the cost per square foot to be kept within the limits of that of the former structure built entirely of wood. At the same time considerable economy has undoubtedly been secured, as far as maintenance costs are concerned.

It seems to the writer that still further economies in maintenance costs might be secured by the use of creosoted timber piles and caps, in order to avoid the renewal of the upper portion of the untreated piles and to maintain a fairly stiff structure. There is a possibility that bench-capping throughout the structure may weaken its resistance to impact from vessels striking the pier. Another advantage to be secured by the use of treated timber would be insurance against the action of sea worms.

Fortunately, at the present time, New York is surrounded by water, the impurities in which do not permit the *Teredo navalis* or other sea worms to exist. Conditions may change, however, and, in the East River particularly, much harm might result from the removal of sewage and other wastes which keep the water impure. The great quantity of fresh water in the North River would probably make the danger from worms more remote, even if the impurities were largely removed. The writer believes that this explains why timber piles are not affected in the immediate vicinity of New York. An experience which he had some years ago on railroad construction work along the Connecticut shore showed that yellow pine timber could not be kept intact much longer than one year. Certain piling was removed fourteen months after it had been driven and, with the exception of a core in the center of the piles about 4 in. in diameter, was found to be riddled by worms. This would seem to show that, but for the impurities in the water, the same thing would take place in the untreated timber piers in New York Harbor.

Mr. Beugler.

The adoption of all-concrete piers is probably quite remote for New York. The uncertainty as to the life and durability of plain or reinforced concrete piles in sea-water makes it inadvisable to invest a large amount of capital in such structures until their durability is proved beyond a doubt. At the present time it is believed that, if impermeable concrete can be secured, there will be little or no question of durability, but practically it is almost impossible to secure this class of work. The question of rigidity and the inability of a concrete structure to withstand shock seems to be a serious one, but not unsurmountable. Some of the concrete piers constructed along the Pacific Coast and elsewhere have special provision for absorbing the impact. One scheme, which appears to have worked fairly well, consists of a number of steel springs quite similar to those used in freight car construction, placed along the edge of the deck, with a long distributing timber instead of the usual fender construction. At other places the concrete construction has been faced with a line of spring piles arranged so that the piles absorb the shock before the bearing comes directly against the concrete deck. Even with the timber type of pier construction, it is quite necessary to secure a rigid structure, particularly where the pier is covered by a permanent superstructure of some size.

One interesting point brought out by the author is the development of the water-front from a distinctly business standpoint, that is, on the basis that all expenditures for improvements shall return a reasonable rate of interest on the investment. This has not always been the rule in the case of expenditures for public works, for which funds are apparently more easily secured than for private enterprises.

Mr. Taft.

HARRISON S. TAFT, ESQ. (by letter).—Mr. Staniford's invitation to present a written discussion of this valuable paper is accepted by the writer, perhaps with a little hesitation, as he feels that he may be "rushing in where angels fear to tread." A full discussion of the concrete dock problem would be so extensive and would lead into so many phases that it would be impossible to cover the subject thoroughly in a single article. Mr. Staniford treats of only one special phase of the problem. For several years the writer has been making a deep research and study of the whole subject, not only as developed in foreign countries, but as worked out thus far in domestic construction. The results of this research are being compiled in a rather extensive treatise or paper to be entitled "Concrete Docks," but as it is impossible to make the entire results of this research a part of this discussion, the writer will state simply a few of the facts, as therein recorded, in order to bring out the different phases of the subject.

Those who have studied the subject are no doubt aware that the first and most important question that confronts the engineer is the practicability of using concrete in sea water. There can be no denying the fact that, in attempting to make such use of con-

Mr. Taft. crete, there have been many disastrous failures. These have been due not as much to the design of the structure as to the use of unsuitable material and improper methods of placing the concrete, on which too much stress cannot be laid.

For structures in sea water, the whole subject reduces to the importance of obtaining a cement which possesses the inherent property of resisting the disintegration due to the chemical action of magnesium and the sulphate contents of ocean water on the alumina compounds in the cement; and also of obtaining an impermeable concrete without the use of any of the so-called water-proofing compounds. Such a cement must be low in alumina and high in silica; it should be of a slow-hardening but quick-setting type, and also of a fine pulverization, with no free lime. From the great success obtained by the use of foreign cements in structures placed in sea water, it is very evident that the German manufacturers solved this important question long ago. From the large number of various ideas of which one reads in American technical papers, it would appear that the manufacture of a domestic cement suitable for use in sea-water concrete is in the embryonic stage, the ideas as to the facts of the question being almost as numerous as the different brands of cement.

Although to the average concrete engineer the chemical composition and physical structure of the stone, sand, and gravel for use in proposed sea-water concrete structures would seem to be of minor consequence, it is a fact that such questions must be given the greatest consideration, if such concrete is to be of a lasting quality. It is of the utmost importance that such a concrete should have a maximum density. Thus the mechanical combination of the sand, stone, or gravel should be known, and modified to suit conditions as the work progresses. Far better results will be obtained by using a hard trap rock than gravel.

The next phase of the subject that confronts the engineer is the design. In designing a new type of structure one naturally investigates first what others have done along similar lines. Generally speaking, in America the problem is in a very early stage, as it is only natural that a forested country should be the last to take up the development of concrete docks. When the extensive reinforced concrete docks in England, France, Spain, and other European countries are investigated, it appears that this class of construction passed the experimental stage long ago. Especially is this so in England, where the art has reached a degree of perfection far in advance of that in any other country; such a degree, in fact, as to have become almost a standard for other parts of the world. A review of the English concrete docks shows that some have been in successful operation for eighteen years. Their maintenance cost is reported to be exceedingly small. In France, Spain, Italy, South America, and other foreign countries, concrete docks are

to be found, and their number is increasing rapidly. It is to be regretted that time will not here allow a detailed discussion of such an important part of the subject. Mr. Taft.

After the engineer has satisfied himself as to what has been done, the question of his own design stands out before him. There is no doubt in the writer's mind that the average concrete engineer is perfectly capable of designing concrete docks of one type or another which will more than fulfill the requirements for which they are intended; but, in making this design, the question is, what will be the cost of the dock? Thus the design problem reduces itself to a question of cost and the cost problem to a question of reducing to a minimum the quantity of concrete, reinforcement, and all other material, including forms, without diminishing the strength of the structure, an arrangement of beams, slab or otherwise, which will result in a most economical and practical method of construction.

It is unnecessary to impress on the members of this Society the fact that the cost of the design for a structure is but little in comparison with that of the material that goes into it and the necessary labor incident to its construction. As an axiom, the most economical form of concrete construction is manifestly that in which all secondary stresses are reduced to a minimum and all material is performing its utmost duty.

The next phase is, what type of construction shall be adopted for the concrete dock, in order to comply with the foregoing truisms? Shall the dock engineer recommend a full, out-and-out, reinforced concrete and structural steel dock, as worked out at San Francisco and later adopted by the United States Government for its concrete docks in the Philippines and Puget Sound Navy Yard? Or shall he recommend a driven concrete pile with concrete beam and slab-deck type of construction, so common in foreign countries and also found among American concrete docks to quite a large extent? On the other hand, he has the option of proposing a semi-concrete dock of either of two types: (1), wooden piling, plain, creosoted, or concrete protected, with a concrete deck; (2), reinforced concrete driven piles with a wooden decking. Right here Nature introduces another difficulty—the destructive teredo and other marine borers.

In fresh water it is perfectly feasible to adopt untreated wooden piles, with a concrete deck. In New York Harbor, as Mr. Staniford cites, this type of construction can be made a success because the sewage is destructive of the teredo in such waters; but, in the waters of the South Atlantic States, the Gulf States, the Caribbean Sea, and the whole Pacific Coast, conditions are met which have to be overcome by a different type of construction from that worked out so ingeniously under the author's supervision.

Mr. Taft. Another side of the subject is the comparison of wooden with concrete piles, with reference to load-carrying as well as cost and longevity. As a concrete pile will carry approximately three times as great a load as a wooden pile, and, under favorable conditions, can be put in place for about three times the cost of a creosoted wooden pile, would it not appear, in view of the possible long life of a concrete pile in sea water, that a semi-concrete dock—concrete piling and wooden decking—can be built at a reasonable cost compared with an out-and-out wooden dock? In other words, in teredo-infested waters, where a wooden pile dock has a life of about 15 years, a concrete pile dock will last, supposedly, for a whole generation, if not longer.

Though the chemical and engineering sides of the problem have their weight, the most important phase of the subject, in the final analysis, is finance. When a careful analysis of the relative value of initial cost, annual depreciation, fire insurance, bond issues, interest on bonds, and sinking funds is considered, the results are such as to astonish even those who perhaps may be well posted on other phases of the subject. Such an analysis will show that, whereas a wooden dock appears to be a most economical type with which to start, it soon becomes an expensive structure to keep in condition and carry all the overhead charges, especially if such a dock is built on a bond issue, the life of which exceeds the life of the dock, thus resulting in an overlapping bond issue in case the dock is rebuilt. The evils attached to such systems of financiering have been brought home most forcibly in connection with former paving work in New York City streets and with other public improvements. Until harbor development experts fully master the ins and outs of the financial side of the concrete *versus* wooden dock problem, they have another step to take in perfecting themselves in their special line of work.

Perhaps the most interesting phase of the subject, as the writer looks at it, is the construction. As Mr. Staniford has dealt entirely with the designing side of the problem, the writer does not feel at liberty to go into this phase of the question. It is one in which no doubt many engineers are deeply interested.

With this general review of the whole concrete dock problem before him, it was with deep interest that the writer read Mr. Staniford's paper and studied the standard type of construction his department has evolved from the old-fashioned wooden pile, wooden deck docks, a process of true elimination, with each step tested carefully before taking the next one. As the author states that twenty-six such piers have been built during the last 7 years, and adds that they have behaved admirably, it leaves only a small loop-hole for injecting any adverse criticisms of a first-hand nature, as it was during the later stages of the construction period of the Chelsea piers that the writer had an opportunity of witnessing dock work in New York City, although previ-

ous to that time he had been a resident of New York and vicinity for about 10 years. Mr. Taft.

In studying the author's design, the writer could not help comparing it with the so-called Cattle Dock at Liverpool, constructed of wooden piles and wooden bracing, but with a concrete beam and slab decking. As Mr. Staniford states that his type of semi-concrete dock has not been generally adopted by other ports, it would seem that dock engineers hesitate to build a permanent structure on a more or less temporary foundation, especially temporary in teredo-infested waters, in spite of the many excellent qualities claimed for this type, as respects the Port of New York.

When the life of a wooden structure below the high-water line is not endangered by wood-borers, it is quite true that a wooden-pile, concrete-deck dock can be built for a most economical figure; but, how many of our important harbors are free from the wood-boring pest? It would be of interest to know the probable cost of Mr. Staniford's type of dock if the wooden part of the structure were replaced with concrete piles and if a concrete cap were used.

A feature in Mr. Staniford's illustration that attracted the writer's attention was the thickness of the concrete deck-slab, as, in general, it appears to be so nearly that of a well-known flat slab system. On the principle that a dock is a structure carrying heavy floor loads, it is essential to adopt a substantial type of construction. Still, the writer would like to ask the author whether it would not be possible to make his dock still more economical and just as strong by using a shallow type of beam with a wider bent spacing, on the lines of the so-called "Floretyle construction," thus bringing the design into accord with the truisms and axioms previously stated? Or does he depend on his heavy concrete floor slab to obtain sufficient mass in his dock to help resist the lateral thrust from large steamships lying alongside? Not that the writer has any connection with the "Floretyle construction," but he is deeply interested in finding the greatest number of ways to reduce to a minimum the material needed in a concrete dock without decreasing its strength.

Another question: Would it not be possible to design a concrete pile dock with concrete caps and a shallow beam decking which would prove to be fully as economical as that shown on Plate VI, when such questions as depreciation, fire insurance, taxes, interest on investment, etc., are taken into consideration?

At first it would appear that the type of docks shown on Plate VI was lacking in cross-bracing, and that the lateral forces from the pounding of vessels would crack the concrete deck. As Mr. Staniford states that no cracks or other imperfections have as yet appeared, perhaps the heavy 10½-in. slab acts in such a way as to distribute any local lateral forces over a wide area. Still, the writer would be inter-

Mr. Taft. ested in seeing the results if one of the South Brooklyn docks were accidentally rammed by a steamer moving under one bell.

Mr. Staniford speaks of the objectionable feature of the rigidity in a complete concrete structure. If concrete possesses no elasticity, how does the flexibility of his wooden piles prevent the concrete deck from cracking under the force of a lateral blow from a vessel? As the author shows only a short length of piling on Plate VI, he gives no idea as to the depth of the water in which these semi-concrete docks are built, whether in shallow depth, with short unsupported lengths of piling and the slip dredged out, or whether the depth is uniform, such as 20, 30, 40, 60, 70, or even 90 ft., as in Seattle Harbor, and that, too, within 700 ft. of the bulkhead line. Such excessive depth might not give a dock of this type the same rigidity as obtained in the shallower harbors of the Atlantic Coast. Thus it might not be suitable for deep harbors.

Table 1 contains data of great value; it is the only statement of its kind the writer has found in his prolonged research. It would appear from this table that the average annual cost of maintenance and repairs for New York City docks is about 11% of their total cost. In Puget Sound waters, the annual depreciation of a creosoted pile dock is fixed by the valuation experts at 10% of its initial cost. In fresh water a depreciation of 5% is quoted. As good merchantable dock timber can be had, f. o. b. site, in Seattle for about $15 or $16 per thousand, with cement in carload lots at $2 per bbl. at the site, a comparison of cost of an Eastern dock with a lumber dock built in Puget Sound waters is perhaps not exactly equitable. Again, New York docks do not need concrete or treated piles as do those in Puget Sound. As the prices per square foot quoted by Mr. Staniford for the two South Brooklyn docks are practically the same as it is costing to build the new public docks (wooden creosoted piling and complete wooden decking) of Seattle for deep-draft ships, in view of the longevity of the New York type of concrete docks, the comparison is striking. It is the more remarkable because the under-water part of the South Brooklyn dock will last many decades longer than will the creosoted piles driven in the Puget Sound and other teredo-infested harbors.

Mr. Staniford states:

"The attempt at absolute permanency * * * has generally resulted in prohibitive first cost, when considered as a business proposition requiring interest on the capital invested."

He also says:

"It has resulted, in some instances, in absolutely permanent structures at such great expense that remunerative return on the capital invested is highly improbable, if not impossible; in other words, the benefits derived are being consummated at too great a cost, even when considered from the point of view of 'indirect revenue'."

It is perhaps true that when attempts have been made at absolute permanency at other ports than New York, the general result has been an excessive and perhaps prohibitive first cost, prohibitive in the past, except in our largest seaports. Still, full concrete docks have been built, and are still being built in some of our larger Pacific ports, as well as very extensively in foreign countries; but, what of the future? Has the concrete engineer reached the maximum economy in concrete dock design? If so, Mr. Staniford's statement can perhaps stand unchallenged. On this one point, if on no other, the writer desires to cross swords with the author of this valuable paper. It is a question which has been discussed frequently in the technical press of late, but all that discussion seems to be in connection with present and ordinary types of construction, and not along new lines of design—still trying to obtain economy by improving the reciprocating engine rather than by adopting the rotary type. Mr. Taft.

The writer does not wish to inject into this discussion anything that would detract from the interest and value of this paper; but, in compliance with a suggestion by Mr. Staniford, he submits some illustrations, indicating a method whereby it would appear that the maximum economy has not yet been reached in the author's design. An attempt will also be made to convince Mr. Staniford of the possibility of building a full concrete dock, the first cost of which will not be prohibitive. This will be done, not by filing a large number of plans covering various designs for concrete docks, but by submitting just one design wherein the quantity of material has been reduced to a minimum without any reduction in strength, as mentioned previously.

The most ordinary type of concrete construction is the well-known beam-slab system. In such a system the load on the floor is carried to the beams and thence to the supports. The upper three-eighths (approximately) of a concrete beam is in compression, the lower five-eighths (approximately) in tension. In designing reinforced structures, no account is ever taken of the tensile strength of concrete, the primary function of this material being to resist compressive and shear stresses. Steel is inserted to take up the tensile stresses. The concrete below the neutral axis is useful only as a means of holding the steel in position and making it act through shear. Thus it is apparent that more than one-half of the concrete in a beam is not utilized economically to its full capacity, and is therefore a considerable extra burden to the structure, resulting in an increased cost for material, forms, and supports. This waste becomes greater with increased spans and under heavy loading, especially over a water surface where expensive means of form supports are generally required.

During the past years a number of flat-slab types of construction have been brought out, all generic of the first idea, the so-called mushroom system; some of them are nothing more nor less than a shallow-

Mr. Taft. beam system masquerading under the name of flat slab. From reliable data furnished the writer, the thickness of the deck slab of these special types is so great as practically to counterbalance any material saving over a beam system, and it is an open question whether there is an actual cash saving in adopting such flat-slab systems.

Even if more economical, are these various flat-slab systems suited to dock work and the heavy lateral thrust that the docks have to stand? If not, is it possible to produce a new genera of concrete construction, either of a beam, a flat slab, or other type, that will stand in a class by itself and be suitable for dock work as well as for other heavy types of reinforced concrete construction? The writer's answer to the question is shown by Figs. 7, 8, and 9, of which only a brief description will be given at the present time. This system consists of large expanded hollow heads placed at the top of ordinary solid or hollow columns. The heads are of a conical or pyramidal shape, with a center post and diaphragms. Resting on the upper rim of the heads is the flat deck slab, sufficiently reinforced by non-trussed bars running diagonally, longitudinally, and crosswise, as may be necessary. The center post, the deck slab and the flaring sides of the heads form a perfect truss, integrated completely around the axis of the column. The heads should be poured some days in advance of the slab, the slab being poured after the heads have become well hardened. The necessity of binding the heads and the deck slab securely together will depend on the purpose of the structure, that is, whether it is to carry direct vertical loads only, or to absorb lateral shock in addition to a vertical load, as in dock work.

The heads may be likened to spread foundation work, made hollow and turned upside down, or the well-known household tin funnel resting on a firm foundation and supporting a slab or platform on its upper rim. The deck loads are supported by the expanded heads and transmitted through them to the columns and distributed on the piling or hard substratum by the enlarged base at the foot of each column.

This system does away with all the tension concrete below the neutral axis of a beam system. The flaring sides of the heads are in direct compression and shear. Thus all the concrete in the heads acts directly in taking up the stresses due to the superimposed load.

This system not only reduces to the absolute minimum the quantity of concrete needed, but also does away with trussed steel. This results in a structure far more economical than an out-and-out beam and slab system carrying heavy loads.

To absorb the lateral thrust on the dock, a suitable system of bracing of one type or another is provided, as shown. There is also a system of fender piles with their rebuffer springs, the lower spring supposedly absorbing the larger part of the lateral pounding and transmitting it directly to the bracing without any rocking of the heads.

Mr. Taft.

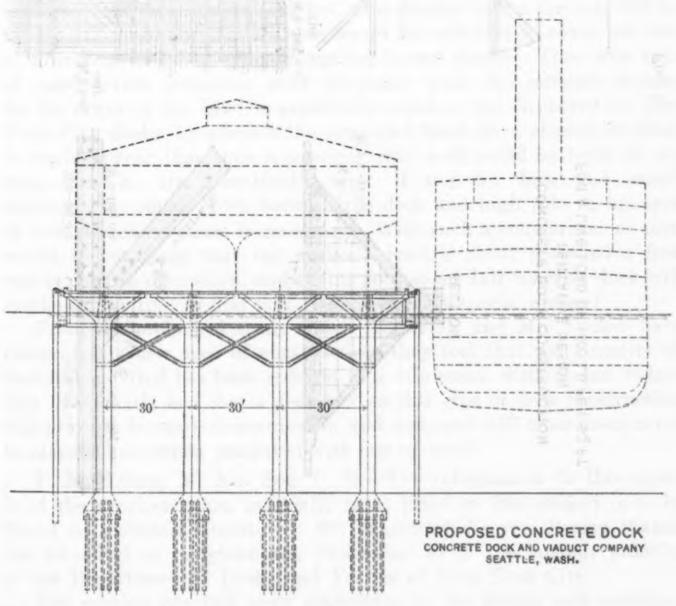

FIG. 8.

Mr. Taft

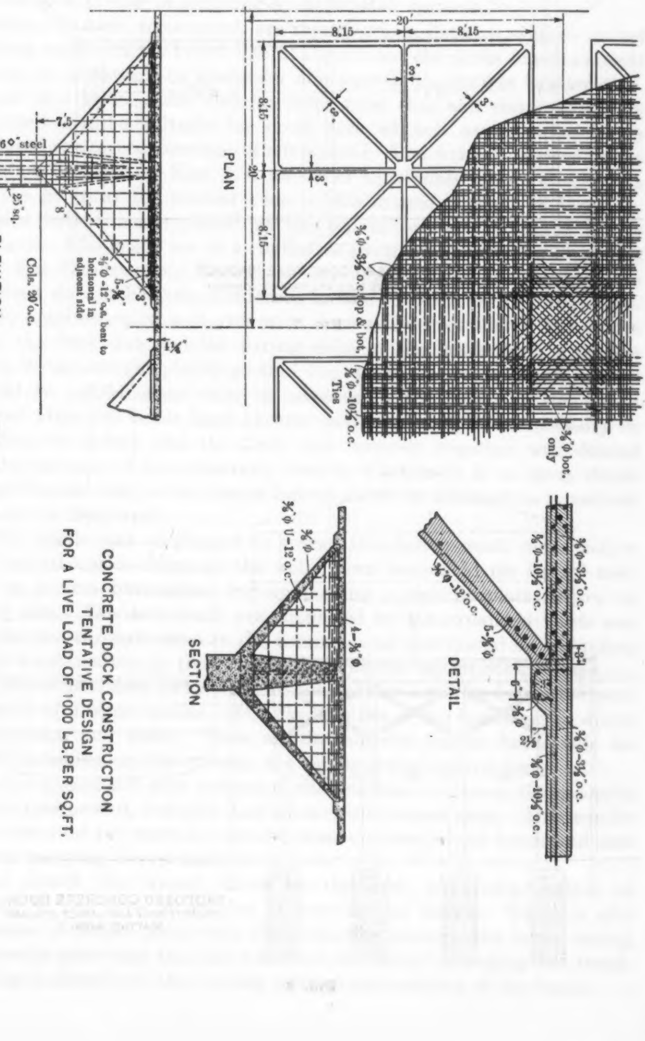

FIG. 9.

CONCRETE DOCK CONSTRUCTION
TENTATIVE DESIGN
FOR A LIVE LOAD OF 1000 LB. PER SQ.FT.

Just a few words regarding the quantity of concrete in such a system as compared with that in a beam and slab type, as the cost of a structure depends to a large extent on the quantity of material that goes into it: A reliable estimate of the quantity of concrete in one of these special structures indicates a possible saving of more than 20% over a standard beam system. Hence, about the same saving in cost would be expected. Mr. Taft.

In order to obtain an unbiased opinion on this special type of construction, the writer engaged H. F. Tucker, Assoc. M. Am. Soc. C. E., a specialist in reinforced concrete, to investigate this design thoroughly in all its many and unusual phases.

Referring to Fig. 9: The structure is designed for a uniform live load of 1 000 lb. per sq. ft. over the whole panel, as compared with 500 lb. per sq. ft. for the author's structure. A careful estimate will show that the quantity of concrete in this special structure for a 20 by 20-ft. panel, exclusive of the column part below the head, is practically 13 cu. yd. The quantity of concrete in Mr. Staniford's structure for the 20 by 20-ft., 10½-in. slab is the same. Inasmuch as the tentative design is for a direct vertical load of 1 000 lb. per sq. ft., perhaps it is not an equitable comparison; but, in a similar design for only 500 lb. per sq. ft., the saving in concrete would be sufficient to cover the cost of providing sufficient bracing against lateral forces. Thus this type of construction compares most favorably with the author's design. As the depth of the head is practically equal to the freeboard of New York City docks, by placing the expanded head on a cluster of piles, it would appear that such a semi-concrete dock could be built at the same cost as Mr. Staniford's type, if not for less, and would eliminate the repair work between the deck and high tide in his type of dock, which he states is necessary. With such a comparison as this, would it not seem that the author's remark about prohibitive first cost is open to discussion, and that a permanent full concrete dock will not be prohibitive in first cost if built on this special design?

From the prolonged study which the writer and Mr. Tucker have made of this new type of construction, they feel that the quantity of material required has been reduced to a minimum, without any reduction in strength, and that a dock having this type of deck construction will prove to be more economical in first cost, and still more economical in maintenance when compared with one of wood.

F. R. Harris, M. Am. Soc. C. E.—The information in this paper is of the greatest value, especially as so little on this subject is to be found in technical literature. Mr. Staniford deserves hearty thanks for his effort to enlighten the Profession as to the current practice of the Department of Docks and Ferries of New York City. Mr. Harris.

The speaker has had some experience in the design and construction of wharves and piers at various ports on the Atlantic Coast,

Mr. Harris. especially in New York Harbor, and feels that it is his duty to invite attention to certain parts of this paper, as his investigations have shown that the conclusions arrived at and implied by Mr. Staniford are not entirely beyond question and challenge.

About four years ago, the speaker made a thorough investigation of certain projected pier or wharf construction at the New York Navy Yard. Several such wharves had been built there, and, under a project for the development of the Yard and the improvement of the water-front, two more were projected, with the probability that these would be followed by the construction of five others. Another wharf, designed by the speaker, of the general type which had been used at the Navy Yard for some time, was just being completed.

Being familiar with the current practice of the Department of Docks and Ferries, he made a careful investigation of the design then used by that Department, particularly the concrete deck on timber piles and caps. It seemed especially desirable to use such a design on account of its reputed economy in first cost and its apparent advantage in being fire-retarding. The results of this investigation were not entirely in harmony with the conclusions set forth in this paper.

It was found that the cost of a concrete deck wharf would exceed that of a timber deck wharf, this conclusion being reached in spite of the contract price obtaining on the City piers at South Brooklyn. The speaker interviewed the contractor for some of these piers, and learned that the price at which they were being built was not a fair criterion, as the cost was considerably in excess of the sum the contractor was receiving. This served to confirm the estimates which had been made, particularly when the figures were taken up with various contractors. It became evident that, if bids were invited for piers or wharves with a concrete deck, and an alternate with a 4-in. deck and 3-in. sheathing on top of it, the cost of the concrete pier would be higher by about 25 cents per sq. ft. The cost of the substructure—the piles and caps—would be practically the same in both types, with a slight modification which will be mentioned later. The superstructure, which could be considered as the deck structure, would consist of rangers, 4-in. decking, and 3-in. sheathing, in the case of timber wharves; of 10½ in. of concrete and 2 in. of asphalt paving, in the concrete deck wharf. The lumber in the timber deck wharf would be about 8½ ft. b. m. per sq. ft., which, at $42 per thousand ($35 for lumber and $7 for labor), would amount to 35.7 cents per sq. ft. This should be compared with 0.03 cu. yd. of reinforced concrete and 1 sq. ft. of asphalt, in the concrete deck wharf, estimated at 60 cents per sq. ft., or about 25 cents per sq. ft. more than the timber deck wharf, which is an additional item in favor of the latter.

The deck structure of the concrete deck wharf would weigh practically 150 lb. per sq. ft., thereby decreasing its live-load carrying

capacity to that extent; the timber involved would only weigh 34 lb. per sq. ft., showing that the timber wharves would have a carrying capacity of 116 lb. per sq. ft. in excess of what the same foundation would carry with a different type of deck. Therefore, in order to make the two systems comparable, additional piles, and probably caps, would have to be provided in the concrete deck wharf, making the difference in cost even more favorable for the timber deck wharf. The speaker fully appreciates the fact that special conditions in taking care of the transportation and shipping of valuable materials in New York City involve fire risk and insurance, and that probably on this account the Department of Docks and Ferries was well warranted in substituting the concrete deck for the timber deck; and although this reason alone justifies its use, it is misleading to justify it on the basis of cost and economy. Mr. Harris.

As an objection to timber deck wharf construction, Mr. Staniford has mentioned the necessity of repairing and relaying the deck sheathing on account of its destruction by traffic. The speaker is also impelled to question the implication that this timber deck sheathing would have to be replaced more frequently than the asphalt wearing surface. From his experience with asphalt pavements, he is inclined to believe that a 3-in. deck sheathing would outlast the asphalt wearing surface, and—even if this conclusion were not entirely correct—that it would be cheaper to repair or replace the 3-in. deck sheathing than the asphalt pavement wearing surface.

Repairs is a very important item, when wharves are not of a permanent type, as is the case with those on timber piles and having either concrete or timber decks. As Mr. Staniford states, it is necessary, at intervals, to replace piles and caps, such repair being caused by decay from mean tide up, except, of course, in harbors where marine borers are found, where a timber pile wharf of any type cannot be considered in any way a permanent structure. The destruction of caps and stringers by rot requires serious consideration, especially as there is a tendency from year to year to deliver commercial timber of poorer quality, containing more sap. It is a well-known fact that inspection rules in relation to commercial lumber have become less and less rigid in recent years. A wooden deck wharf is not considered a permanent structure, and frequent repairs and replacement of the timber work and the piles are expected. These are readily made, as it is not difficult to remove the deck, replace caps, or drive additional piles. The speaker understands that a concrete deck wharf is considered by the Department of Docks and Ferries as more permanent, although why it should be he cannot comprehend, because it is apparent that the timber piles will need repair and replacement just as often as in the timber deck type; the pile caps also will need replacement just as often, and probably oftener, because the concrete slab will

Mr. Harris.

tend to keep the tops of these caps damp and in a condition to invite rapid decay. It will be extremely difficult to make repairs on one of these wharves. The speaker need not compare the task of removing timber planking with that of removing a 10½-in. reinforced concrete slab. The expense of cutting through such a slab, with its reinforcement, will be considerable. It is understood that wharves of this type have not been in use long enough to have required repair, but, when such repairs are necessary, there is no doubt that the difficulty will convince the Department of Docks and Ferries that a permanent deck structure on a temporary foundation is not the very best type to adopt.

There seems to be a generally accepted opinion that there are no marine borers in New York Harbor. This is an error. Marine borers are found in the Lower Harbor, and, perhaps, under certain conditions, which are likely to develop with wind and tide, they will be found on the South Brooklyn shore. A wharf of the Navy Department at Fort Lafayette, constructed about 10 or 12 years ago, was examined recently by the speaker, and preparations were made to repair it. It was found that in many instances the piles were entirely gone, having been destroyed by sea borers, and that the caps and stringers were in such a condition, on account of rot, that it would be an economy to replace the entire wharf with a new one.

In the investigation of pier construction in the vicinity of New York, with the idea of adopting a type for the Navy Yard, as previously stated, both kinds of wharves used by the Department of Docks and Ferries were considered carefully. Previous to that time, there had been used in the Navy Yard a type consisting of a pile platform at low water, surmounted at the sides and ends by masonry retaining walls, the contained space being filled with earth compacted and paved over. The last pier of this type—known as Pier D—designed and constructed under the speaker's supervision, cost about \$3.25 per sq. ft.; this included wood block paving on a concrete foundation, two lines of standard gauge railroad track and one line of 18-ft. gauge, 40-ton, crane track, and also fresh- and salt-water pipes, air pipes, and electric conduits. In making the study referred to, an endeavor was made to reduce this first cost and still obtain a substantially permanent structure. It is apparent, of course, that the pile foundation of such a wharf carries a very heavy dead load, namely, the masonry retaining walls and the 8 or 9 ft. of earth filling; or, in other words, that more than half the foundation piles are used in carrying a dead load, and to that extent are an absolute loss in so far as the live-load capacity of the wharf is concerned. The investigation and estimates established the fact that a timber wharf would cost about \$1.00 per sq. ft., and a timber wharf with a concrete deck, \$1.25 per sq. ft. The items of maintenance and repair

for each type were considerable, and in the case of the concrete deck, the difficulty of such maintenance and repair, entirely eliminated it from further consideration. The speaker, consequently, evolved a design in which he used a reinforced concrete deck, lighter than that of the Department of Docks and Ferries, but, to some extent, similar, and this was carried by reinforced concrete columns resting on a timber substructure. The latter consisted of piles cut off slightly above low-tide datum, and fastened to the cross-caps with oak tree-nails. The reinforced concrete columns were cast on shore. The bases were dovetailed, let into the caps, and wedged to them with spruce wedges. They were also fastended by stringers or clamps which were attached to the caps, and the space between the abutting longitudinal clamps was filled with 3 by 12-in. chocks or filling pieces. The usual brace piles at the side were used in the timber substructure. All the subaqueous work was fastened and wedged, as far as possible, oak tree-nails being used and metal fastenings avoided. The designs were of two types, one with girders and beams to support the concrete deck slabs, and the other using the mushroom system, each column unit being flared out so as to reinforce the criss-crossing of the main deck slab reinforcement. The preliminary estimates indicated that this mushroom type would be less expensive, but the bids received proved this to be in error, and, therefore, the girder-beam type was adopted. Two of these piers have been completed. They have a creosoted wood-block pavement over the concrete deck slab, two lines of standard gauge railroad track, one on each side of the wharf, and two lines of subway, one on each side of the wharf; with fresh- and salt-water pipes, pneumatic lines, and telephone and electric conduits for cables still to be placed. These piers were estimated to cost \$1.60 per sq. ft., but this was based on the use of piles 65 ft. long. On actually proceeding with the preparation of detailed plans, and an investigation of the site, it was found that piles 85 ft. long would be required, and this, together with the expense of inshore connections for pipe work, railroad tracks, etc., increased the price of the work, so that the actual cost of these two piers has been \$2.04 per sq. ft. After the experience gained in the construction of these piers, the speaker is convinced that piers of the size used in New York Harbor, and without the subway and pipe lines, track work, etc., could be constructed for less than \$1.60 per sq. ft. Mr. Harris.

It is apparent that piers of this type may safely be considered permanent, as far as concrete immersed in salt water is permanent. Every precaution which experience at the Navy Yard could suggest was taken to make this concrete work permanent, but so much difficulty has been had there with concrete in salt water as to suggest that this is not a permanent material in salt water. Dry Dock No. 2, at the New York Navy Yard, was originally built of timber, and

Mr. Harris. after very voluminous discussion before this Society, years ago, condemning timber structures of this sort, was rebuilt partly of concrete. It is now undergoing extensive repair. Considerable sums are being expended in replacing the facing of the concrete altars and floor, which has deteriorated and disintegrated to such an extent that it is possible to use a pick and shovel in removing the concrete.

The concrete unit columns in the wharves mentioned were cast on shore, a 1:2:4 mixture being used, containing a water-proofing compound. They were allowed to season for some time before being placed in the water.

The speaker's principal motive in discussing this paper is to call attention to the fact that the design used by the Department of Docks and Ferries is a composition of a permanent and a temporary structure. Special attention is called to the fact that it would be difficult or impossible to repair the temporary part—the foundation itself—without also destroying the permanent part, thus making the entire structure only temporary. He also desires to bring out the fact that, with slight additional expense, the permanent part of the structure could have been carried down to mean tide level, thus making the entire wharf permanent, as far as wharf structures of this character and of concrete can be permanent. In other words, in the upper part of New York Harbor, where timber piles will not be attacked by sea borers, and can be considered permanent from low tide down, the composition of timber and concrete, if made as described for the Navy Yard, furnishes a permanent structure at a low first cost. The speaker gladly acknowledges that the investigation made by him first brought to his attention the inconsistency in Mr. Staniford's design, and in an effort to retain its good features and at the same time avoid the expense of reinforced concrete piles, he succeeded in evolving the design he has described.

In reply to Mr. Snow: The speaker does not think that conditions in southern yards can be compared with those in the New York and Boston Yards. He believes that, in southern waters, concrete is free from deterioration partly because of the absence of extreme temperature changes which open up hair-like cracks in the surface, thus permitting the entry, or the attack, of salt water. It has also been stated that a gelatinous substance forms on the face of the concrete, between high and low water, and protects the surface. The speaker believes that even a very thin facing of granite will protect a structure from deterioration, although the joints, after a while, will require re-pointing.

Mr. Snow. J. P. Snow, M. Am. Soc. C. E.—There are many examples of concrete construction in sea water in Boston Harbor, and in every instance known to the speaker there has been serious disintegration be-

FIG. 10.—DISINTEGRATION OF CONCRETE, ABUTMENT "Q", VAUGHAN'S BRIDGE, PORTLAND, ME. ONE WINTER'S EXPOSURE. CONCRETE IN LOWER PART PROTECTED BY SAND. SLOPE OF SAND FILL SHOWN AT LOWER LEFT CORNER.

FIG. 11.—ABUTMENT "Q", VAUGHAN'S BRIDGE, PORTLAND, ME.

tween high and low tides. This trouble is attributed to the action of frost. The damage is readily repaired with a cement gun, if not allowed to become too extensive. It would be of great interest to ascertain if this sort of disintegration occurs in southern waters where there is no freezing, and the speaker would be glad to have Mr. Harris state, if he knows, whether Government works of this class suffer between high and low tides in southern harbors. Mr. Snow.

Mr. Shertzer. TYRRELL B. SHERTZER, ASSOC. M. AM. SOC. C. E.—In 1906, the concrete was placed for one of the abutments of a large highway bridge across the Fore River, a branch of the Harbor of Portland, Me. This abutment was constructed with a concrete base, granite facing, and concrete backing. The plans called for a sand-fill to be placed across the front and ends of the structure to a little above the elevation of the bottom of the granite, this fill to be paved so as to resist wave action. Conditions were such, however, that all the fill could not be placed before cold weather set in.

The winter of 1906-07 was a severe one, and it was noticed that the unprotected concrete base was disintegrating where exposed. In the spring of 1907, after the ice had gone out, the exposed surface was found to be disintegrated to a depth of more than 2 in. That portion of the concrete which had been protected by the sand, however, was found to be in perfect condition, and, at the elevation of the sand protection, there was a sharp and distinct limit to the area disintegrated. It will be seen clearly from Fig. 10 that the portion of the concrete below the sand line still shows the saw marks of the form boards, whereas that portion above the sand line is badly disintegrated. The small hole seen at the upper right-hand corner of the photograph was drilled for the purpose of ascertaining how deeply the concrete was affected. The slope of the edge of the sand-fill, which was excavated to permit of taking the photograph, may be seen at the lower left-hand corner. This photograph shows a portion of the same face of the base as appears in Fig. 11, the photograph of the entire abutment.

These conditions led to a series of experiments to ascertain, if possible, the causes of the phenomenon. In the fall of 1907, several sets of standard briquettes were made of both neat cement and of a 1:3 mix, making all the possible combinations of mixing with fresh and sea water, and using the local bank sand and standard Ottawa sand. Three 12-in. cubes were also made of samples taken from the regular machine-mixed concrete. These briquettes were made and placed at the beginning of cold weather in the winter of 1907-08. They were distributed as follows: Sets of three briquettes of each type and enough for the regular 7-day, 28-day, 3-month, 6-month, and 1-year tests were stored in the laboratory in fresh and sea water;

Mr. Shertzer. buried in the sand at a depth of about 1 ft. above high water, at mean tide, and below low water; and placed in crates above high water, at mean tide, and below low water. One cube was placed on the flats above high water, one at mean tide, and the third was lowered to the bottom of the river.

Chemical tests were made during these experiments by the professor of chemistry at the Portland High School to ascertain the effects of the materials and water.

Unfortunately, the long-time tests could not be made on the briquettes, as the City Hall at Portland was destroyed by fire early in 1908, and the laboratory and all the records and data were lost, so that what appears here is from memory only.

Such of the tests as were made showed that the briquettes stored in both fresh and sea water in the laboratory, those buried in the sand, and those exposed in the crates above and below water, gave practically identical results, and those stored in the crates at mean tide were entirely disintegrated after from 2 to 3 weeks of exposure to freezing weather.

The large cubes were made and placed in the spring of 1907, and were exposed throughout the summer of 1907 and the following winter. No effect was observed as the result of the summer exposure, and after about a year's exposure those cubes placed above and below water were still in perfect condition, the one exposed at mean tide, however, had been reduced to about 4 in. as the result of exposure during the winter.

In the spring of 1907, as soon as weather conditions permitted, the loose material was removed from the disintegrated face of the base of the abutment, the surface was plastered up, and the rest of the sand-fill and the pavement placed. In the fall of 1912 some of the rip-rap and sand protection was removed, and it was found that the trowel marks in the plaster used in smoothing up were still distinct. The sand lying within the tidal range has been saturated with sea water for more than 5 years, and it would seem that if the action were a chemical one it would have affected the concrete.

It would seem that the only conclusion which can be drawn from the above-mentioned experiments is that the disintegration was caused by purely mechanical means, and that if the concrete is protected from the direct action of alternate freezing and thawing, such as occurs within the tidal range, there will be no disintegration.

William H. Burr, M. Am. Soc. C. E., was the Consulting Engineer, and the speaker was Resident Engineer, on this work.

Mr. Stengel. C. H. Stengel, Assoc. M. Am. Soc. C. E.—In 1907, when the Virginian Railway coal terminals were constructed, it was necessary to build permanent foundations for the large steel superstructure, which

extended 1 000 ft. into the waters of Hampton Roads. Open pile foundations, capped with grillages, were out of the question, as the waters were infested with teredo. The design decided on was monolithic concrete piers, with heavy rectangular bases, built on piles in 30 ft. of water, the piles being cut off 1 ft. below the mud line. On the rectangular bases, battered pier sections were built to a level approximately 4 ft. above high water. All this concrete was deposited under water by tremies 12 in. in diameter, and allowed to set for several days; then the forms were removed and the sheeting was pulled. Mr. Stengel.

Under the conditions existing at the time, and on account of the manner in which this work was done, if there were any chemical action to deteriorate concrete, due to the effect of sea water, it would have been noticed, as a careful inspection of all the piers was made by divers; also, if there was any destruction between high and low water, due to changes in temperature and freezing, it would now be perceptible; as it is, these piers are in as good condition as when built.

The speaker, however, does not doubt that in piers built under similar conditions in northern harbors, where the temperature changes are considerable, and alternate freezing and thawing takes place between high and low water, some mechanical destructive effect might be experienced, as concrete built under the conditions stated never becomes dry, and the contained moisture, in freezing near the surface, would expand and gradually disintegrate the concrete.

This effect, however, should not obtain with concrete blocks, built and matured on land and then set in place between high and low water; and there are a number of examples around New York Harbor to substantiate this statement.

The mixture of concrete used in the construction of the foundation for the coal piers was 1 : 2½ : 5, with gravel.

L. D. Cornish, M. Am. Soc. C. E.—The question of the deterioration of concrete in sea water, naturally, was one of the first subjects of investigation by the designing force of the Isthmian Canal Commission in connection with the locks for the Panama Canal. Mr. Cornish.

Data on this subject were collected for about two years and, after careful consideration, the conclusion was finally reached that recorded experience failed to show that deterioration of concrete might be expected in tropical sea water, provided ordinary care was exercised in the selection of the ingredients, and in the mixing and placing.

Experience on the Isthmus, thus far, has shown no reason for a different conclusion, and the speaker is of the opinion that the causes for authenticated cases of deterioration must be sought in mechanical action or poor materials, rather than in chemical action of ordinary sea water on first-class American Portland cement concrete.

Mr. Le Conte. L. J. Le Conte, M. Am. Soc. C. E. (by letter).—Extensive harbor improvements call for strict economy in first cost and annual maintenance, and length of life. Recent developments on San Francisco Bay have given rise to some new features which may be interesting. The final conclusion is that a solid-mole development is much superior in every respect to the ordinary pier, when a wide view is taken of the whole situation from both financial and commercial standpoints.

As the waters of San Francisco Bay are largely infested with the marine pests, teredo and limnoria, all important structures are made of creosoted piles or concrete piles and superstructure.

First Case.—An Ordinary Pier.—For ample commercial purposes, the pier should be at least 200 ft. wide and 1 000 ft. long, with a slip alongside, 300 ft. wide, for handling the shipping, and, without any warehouses, tracks, derricks, movable cranes, etc., would cost probably $315 000.

Second Case.—A Solid Mole.—The mole would be surrounded on three sides with a 50-ft. commercial wharf. The same amount of money will build a solid mole, 500 ft. wide and 1 000 ft. long, and a slip alongside, 400 ft. wide, for handling vessels. This simple structure, like the pier mentioned, is supposed to be without warehouses, tracks, derricks, movable cranes, etc.

A little consideration will show the advantages of the mole development. The dock frontage of the pier development is 2 500 lin. ft.; that of the mole development is 2 900 lin. ft.—a difference of 16% in favor of the latter. In the case of the mole the area of dock flooring to be kept in efficient repair is only about 60% of that of the pier development, which is quite an important item of annual expense. Besides these advantages, the mole has nearly twice as much warehouse room, and a 200-ft. roadway in the center for railway and general commercial traffic, the paramount convenience of which cannot be overestimated.

Mr. Davis. Chandler Davis, M. Am. Soc. C. E. (by letter).—New York Harbor, without doubt, is the most important one in the world. It possesses many advantages over other seaports, not the least of which is the small range of tide. As tidal and wet basins are unknown, these expensive constructions are eliminated from the problem. The current in the river is not so strong that the largest ships cannot be warped into their slips without much difficulty, although at times it may require several hours—it took 5 hours to dock the steamship *France*. Such cases, however, do not occur so frequently that the pier and slip system should be condemned, for it is, without doubt, the best and most economical layout which could have been adopted. It permits the handling of more ships in a given length of river-front than any other plan.

If the scheme adopted at Antwerp had been introduced at New York, a steamship of the dimensions of the *Imperator,* would require about 1 000 lin. ft. of bulkhead for docking purposes; with the plan used in New York Harbor this length of river-front is sufficient to permit the working of four such ships simultaneously. The late General McClellan, the first Chief Engineer of the Dock Department, was wise in developing and perfecting the system he found in use. **Mr. Davis.**

The Hudson River has been encroached on to such an extent that the War Department has finally decided that the pier-head line must not be moved farther out into the river, and all encroachment must be stopped. This attitude of the Government is well taken. When one considers the size of the modern ship, he will realize that, if such extension were permitted, there would soon be insufficient width of clear water to allow the safe handling of these vessels, for at least two ship lengths are required to turn them. At the present time there is barely the necessary width left between the pier-heads, and there is great difficulty in handling the ocean liners. If relief is required, it must be sought by moving the bulkheads inland or locating the docks at points other than on the Manhattan shore of the Hudson River.

The naval architect is increasing not only the length of ocean liners, but also their beam. This is a very important factor, and must be considered in laying out new work. Fig. 12 shows the average increase in beam of ships, for every five years from 1865 to date; it will be seen that it has been more than doubled. The *Labrador,* launched in 1865, had a beam of 39.2 ft.; the new Hamburg-American liner, *Vaterland,* will have a beam of about 100 ft., or two and one-half times that of the *Labrador.*

The open water between two adjoining piers, called the "slip", should be of sufficient width to allow the working of two steamers in the same slip at the same time. The following formula will determine the required width, provided railroad car-floats are not used, as is the case with fruit ships:

$$W = 2F + 4C + 2B + 2L + 50.$$

W = the required width of slip;
F = the width to be allowed for the fender system of the piers, including the rolling log, if one is used;
C = the extreme width of the coal barges;
B = the beam of the ship;
L = the extreme width of the cargo lighters; all expressed in feet.

In the center of the slip, a width of 50 ft. of open water is required to facilitate the handling of the lighters and scows without interfering with the working of the ship.

Mr. Davis.

The general tendency is to sacrifice the slip in order to build large, imposing piers. A width of 90 or 100 ft. for a pier is ample to care for the cargo of the largest ships afloat, and it is quite unnecessary to exceed this, unless it is intended to use such piers as store- or warehouses.

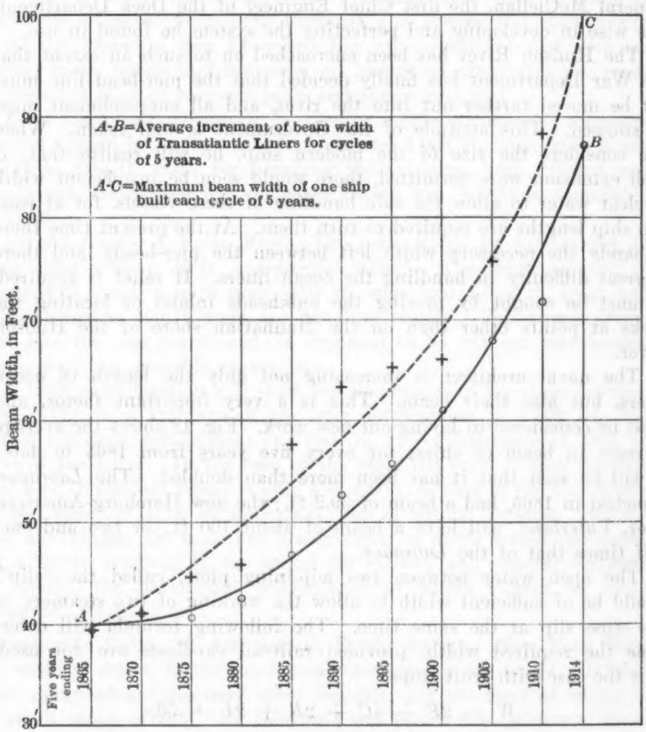

FIG. 12.

Ships of the *Imperator* or *Vaterland* type, having a beam of about 100 ft., would require slips about 400 ft. wide, if two such ships are to be docked in the slip at the same time. These points should be carefully considered in laying out a plan for docks, as congested slips increase the cost of handling cargoes and coaling. The dimensions of the largest vessels trading with the port must be considered in the design, and a study must be made of their gradual increase in size.

The materials which enter into pier construction are many. For a long time only wood was used, but recently the wooden decks and rangers have been replaced with concrete. The North German Lloyd Steamship Company was the pioneer in such work in this part of the world. After the disastrous fire which destroyed its Hoboken docks, the plant was rebuilt with concrete decks and fire-proof superstructures. This scheme has been still further developed by the City of New York, and to-day the construction above the caps or clamps is of reinforced concrete. This construction, however, leaves the piers vulnerable between low tide and the deck. The Hudson River is free from the *Teredo navalis* and other wood-destroying borers, and will probably remain so until some other method is found of disposing of the tons of filth which are daily dumped into the river. The piles below low water, therefore, are, for all practical purposes, indestructible. The few points where protection against worms has been found necessary need not be considered here. In all sections of the port, however, the piles above mean low water will deteriorate and eventually will have to be replaced. The present design of decking used by the City will make such work expensive and extremely difficult. The design, therefore, should include the entire pier from low water up, if it should be desirable to continue the use of wooden piles. A general plan for this could probably be worked out, and would only need to be modified to suit local conditions. Mr. Davis.

The Dock Department is working along the right lines, and is attacking the problems, as they present themselves, in a conservative, but thorough manner.

R. T. BETTS, M. AM. SOC. C. E.—In the type of pier for single-story sheds, developed and built successfully by the Department of Docks under Mr. Staniford's direction, concrete is used for the deck only. Therefore, there can be no question about its durability, as far as exposure to sea water is concerned. In the type of pier for two-story sheds, pedestals of mass concrete, deposited *in situ* on a pile and timber foundation, will support the shed columns. With regard to the durability and permanency of Portland cement concrete exposed to the action of sea water, to which Mr. Harris has referred, the speaker would be inclined to condemn the use of concrete for such exposure, if the experience of the Department of Docks had been as unfortunate as that of the Government, as exemplified by the sea-wall at the New York Navy Yard, and elsewhere. Mr. Betts.

Since the establishment of the Department in 1871, Portland cement concrete has been used in block form and in mass, in the construction of the bulkhead or sea-wall. For the most part the wall built along the shores of Manhattan Island consists of large concrete blocks made in the proportion of 1 part cement, 2 parts sand,

Mr. Betts. and 5 parts $2\frac{1}{2}$-in. broken stone, by volume, and reaching on the face of the wall, from a prepared foundation of concrete in bags on rock bottom at a depth of from 15 to 40 ft. below mean low water, or from a pile foundation sawed to a grade of about 15 ft. below mean low water, up to about $2\frac{1}{2}$ ft. below mean low water, the remainder of the face, up to the street grade, consisting, usually, of granite backed with concrete. In the fabrication of these concrete base blocks no attempt whatever was made to produce a dense face, except the usual "spading" along the form. They were allowed to harden thoroughly in air, and their use has resulted in permanent construction. About 5 or 6 months ago, two of these base blocks were removed from the wall at the foot of East 38th Street, East River, in order to enable the New York Edison Company to place an additional intake tunnel. An examination of these blocks, after a submergence of 10 years, showed perfect surfaces. There can be no doubt as to the permanency of Portland cement concrete when moulded in blocks and allowed to harden in air before being exposed to the action of sea water.

Numerous examples (many of them built by the Department of Docks) of concrete deposited *in situ* and exposed to tidal action, such as concrete walls on rock, concrete walls on pile and timber platforms, concrete walls as facing for timber cribs, and concrete foundations for ferry buildings, exist in and about New York Harbor. A personal examination of many of these structures has shown that in nearly every case where deterioration is found, it has occurred in a zone extending from about mean low water to about mean tide, and, as might be expected, walls exposed to considerable wave action show greater deterioration within this zone. It is also observed that where the precaution has been taken to face up the wall with a richer (1 part cement to 2 parts sand) and denser mixture, from 3 to 6 in. thick (as in the case of the Whale Creek wall, and the Wallabout wall adjacent to the New York Navy Yard), the exposed faces are intact, although it must be stated that the Wallabout wall was not exposed to tidal action until after the concrete had had time to become well hardened.

From the nature and location of the deterioration, there can be but little doubt that it is due in the beginning to a dislodgement of the cement by the action of the water before it has had time to set, and its further progress is due to mechanical action, such as frost, ice, and impact from floating débris, rather than to chemical action. In order to prevent spreading, repairs are made, cheaply, easily, and effectively, by cutting out the affected places to a depth of about 2 in. on a falling tide and replacing them with a mixture of 1 part cement to 2 parts sand.

The speaker has no hesitation in saying that good and permanent mass concrete, exposed to the action of sea water, can be obtained, provided the usual, fundamental precautions for concrete work are observed, as follows: Mr. Betts.

(*A*)—*Design.*—All surfaces of concrete deposited *in situ* and exposed to water should be composed of a dense, rich mixture of 1 part cement to 2 parts sand, from 3 to 6 in. thick, depending on whether or not it is exposed to wave action in addition to frost, ice, and floating débris. All edges should be rounded or beveled.

(*B*)—*Proper Materials.—Cement, Sand, Stone, and Water.*—The Department specifications for cement require that it "shall not set within half an hour after being mixed with water and shall set within five hours. * * * The fineness shall be such that the percentage of cement passing through a No. 100 sieve shall not be less than 95%." The tensile strength as developed by briquettes of neat cement should be 500 lb. per sq. in. for 1 day in air and 6 days in water, and 575 lb. per sq. in. for 1 day in air and 27 days in water. For a mixture of 1 part cement to 2 parts standard quartz sand, the values at the before-mentioned times should be 225 and 300 lb. per sq. in., respectively. The cement is subjected to the usual "pat" tests for checking, cracking, distortion, and color.

The sand should be clean and sharp.

The stone should be clean, hard, and durable. Gravel should not be used as a substitute for broken stone, except possibly, in "backing" concrete, where it will not be exposed to tidal action.

The water should be fresh and clean.

(*C*)—*Workmanship.*—All ingredients should be mixed thoroughly so as to form a "wet" mixture, and care should be exercised in depositing it so as to get a uniform distribution of the ingredients, without "pockets." "Facing" should be deposited simultaneously with the "backing" and in such a way as to make the mass monolithic. Concrete, especially the exposed surfaces, should not be deposited in water, but the work should be planned and executed so as to keep the depositing in advance of a rising tide. Forms should be carefully made, preferably of dressed, tongued-and-grooved lumber, treated with crude oil or similar material to prevent adhesion of the concrete, and made tight enough (caulking the joints if necessary) to exclude water from the moulds, especially on a rising tide. They should be designed and braced so as to retain their shape accurately, even should it become necessary to fill a mould rapidly.

All concrete surfaces should be kept wet with fresh water for at least a week, in order to insure the proper initial hardening of the cement.

In hot weather, if exposed to the direct rays of the sun, the work should be covered with tarpaulin or similar covering and kept moist to prevent "drying out."

Mr. Betts.

In freezing weather the concrete materials should be heated, not only for the immediate purpose of mixing, but for keeping the frost out of the materials as well. The water should be kept hot, but not boiling; and all concrete deposited during freezing temperatures should be immediately covered and protected from frost until setting is assured.

Walls of mass concrete, requiring the depositing of concrete under water within forms, should not be attempted, unless the enclosing structure or forms are allowed to remain and become a part of the permanent construction, as it is practically impossible to obtain proper surfaces with concrete thus deposited.

Mr. Staniford.

CHARLES W. STANIFORD, M. AM. SOC. C. E. (by letter).—Some of the discussion has wandered into questions not germane to the subject matter of the paper, and has entered into matters pertaining to harbor design and general methods of construction.

The particular object of the paper was simply to show what had been accomplished by the Department of Docks in producing something more permanent than the ordinary New York wooden pier, and at about the same cost.

It is the writer's opinion, however, that all the discussions are valuable, as they bring out many admirable points in connection with harbor design and general designs for actual construction.

It is repeated that the old wooden pier, as built in New York Harbor up to 10 years ago, because it was easily removed and reconstructed, was one of the greatest factors in developing the harbor facilities. Instead of the shipping being compelled to adapt itself to the location and operation of massive permanent structures located along the water-front, as in English and Continental harbors, where there are stone quays and piers, the structures for berthing vessels and taking care of cargoes in New York Harbor were located to meet the conditions of shipping as these conditions developed and increased facilities were required. As the size of the vessels increased, the docks grew larger, in width as well as length, in proportion to the width of the slips, that is, the distance between piers increased to accommodate the greater beam of ocean steamers. It can readily be seen that if the New York water-front was lined with a system of massive and permanent stone, steel, or concrete structures, the development of the harbor could only proceed at enormous expense, and consequently with much less rapidity than is made possible by building structures of lighter form. The type formerly built by the Department met for the time all requirements, but, at little added expense, many objectionable features of the former construction have been eliminated, thus doing away with constant repairs; and, for the present, at least, the Department has a type which is durable and at

the same time inexpensive, and admirably meets the present-day demands of shipping. The result of this more modern method of construction has been shown in the paper, and the figures substantiating the statements are based on fact, not conjecture. Mr. Staniford.

Mr. Harris questions the lasting qualities of the asphalt wearing surface, and infers that a 3-in. deck sheathing would outlast the asphalt. The experience of the Department with deck sheathing is absolutely as cited in the paper, and not a matter of inference. Repairs to New York piers are absolutely needed at short intervals, resulting in frequent renewal of the whole deck sheathing, the wear on the latter being the result of a traffic movement probably unequaled in the world. In fact, this whole paper deals with conditions of this kind, where structures are under intense use constantly, and not with docks built in Navy Yards or in any place for public function, where team traffic is almost unknown, or where the docks are practically intended as a berthing place for steamers while undergoing repairs.

As a concrete illustration of the inexpensiveness of the asphalt wearing surface, the piers of the Chelsea Section may be cited. On these nine piers, each approximately 800 ft. long and 125 ft. wide, asphalt wearing surfaces were laid, and for a period of 5 years, under the most extreme traffic conditions, no repairs were necessary. Under the contract for this work, 96 989 sq. yd. were laid, and a bond for 5 years was given to maintain the asphalt wearing surface; at the expiration of this 5-year bond period, repairs were only needed on 780 sq. yd., costing $800, or less than 1% of the total cost. From the expiration of the bond period to the present day no repairs of these surfaces have been necessary; and, furthermore, no repairs are needed at the present time. Fourteen other piers may be cited where the same result has been secured by the use of asphalt.

As stated in the paper, for light traffic, this asphalt wearing surface may be eliminated, but, for heavy traffic, it has been found absolutely necessary to put some deck wearing surface over the concrete; and in some other localities the writer has advocated wood block or brick pavement for this purpose. Granite block pavement has been considered, but was not adopted because it would add so much to the weight.

Mr. Harris questions the facility of making repairs to decks of this kind. These repairs, like all others relating to dock and harbor structures, must be made by specialists in work of this class. The Department force, consisting of twenty pile-drivers with their crews, is constantly engaged in doing just such work.

It is mentioned that the eventual destruction of caps and stringers by continuous repairs deserves consideration. This is just what was considered in the design of piers of this style. By eliminating all the stringers and all the deck, leaving practically little more than the

Mr. Staniford.

timber caps, the quantity of timber to be renewed is reduced to an absolute minimum, the life of the caps, in addition being prolonged considerably by the use of the new system with its water-proof deck. In time, when repairs to this composite structure are required, owing to the rot of this insignificant quantity of timber underneath, such repairs will not necessitate the disturbance of the concrete deck, as all the work may be done below it by simply supporting the structure between alternate pile rows, removing the caps, and bench-capping the piles, the usual method by which similar repairs have been made by the Department for 25 years or more.

The repair of an occasional pile in the interior of the pier, on account of rot, is accomplished without any trouble by cutting the pile and replacing the head by bench-capping or splicing, thus making the structure as strong as the original. This has been done in a number of instances in New York, even under elaborate buildings, such as ferry houses, without any trouble whatever, and without any interruption of traffic.

The design of this pier offers relief from constant repairs, and makes unnecessary the expense of actual reconstruction from mean low water up, for the experience with the asphalt deck surface has covered a sufficient time to prove that repairs have been greatly eliminated by this feature, and the structure is actually preserved by the asphalt deck surface. Mr. Staniford.

The writer gave what he considered to be full recognition to the design of the piers being built in the Brooklyn Navy Yard, as being a good type for producing an absolutely permanent structure in these waters. To produce anything in the line of permanent development, however, is simply a question of expense. Mr. Harris has given some figures relative to the cost of piers in South Brooklyn, and has inferred that these prices were not a fair criterion, it being contended that the piers were built at extremely low cost, and with no profit to the contractor. This contention is difficult to prove. In the paper, the cost data for these piers are correct, and are repeated and elaborated as follows: The 31st Street Pier was let to the lowest bidder at $174 587. This was one of twelve bids, the next four higher being: $183 820, $192 462, $195 897, and $196 725. The 33d Street Pier was let to the lowest bidder at $236 500. This was one of seven bids, the next three higher being: $244 587, $246 332, and $254 897.

In each case the bidders for these piers were among the most reliable dock-building contractors in New York; and without question, any one of them could have performed the work successfully for the amount of his bid.

The New York Department of Docks has developed many designs for absolutely permanent structures, not only on the lines of the piers in the Brooklyn Navy Yard, made permanent from low water up, but absolutely permanent structures with concrete piles, and various forms of filled-in piers, some of which are without doubt as good as those cited. In any event, no two designs are exactly the same. Where the money is available, and the cost of deck repairs will necessarily be slight, and where a permanent structure is warranted, Mr. Harris is unquestionably right in suggesting that the structure should be made permanent from low water up.

Mr. Harris states that the generally accepted opinion that there are no marine borers in New York Harbor is in error. He states that they are found in the Lower Harbor, and that perhaps under certain conditions they may develop with wind and tide on the South Brooklyn shore. The writer fails to see why he cites the fact that he had found sea borers at Fort Lafayette. This question of the presence of the teredo, limnoria, or other wood-boring animals was settled by the Department more than 40 years ago. In fact, it was not only settled by the Department, but by all the corporate interests which have helped to build up New York Harbor while spending several hun-

Mr. Staniford. dred millions of dollars in building wooden structures. Unquestionably, if New York had remained a settlement with none of the evils attendant on the growth of a city of even ordinary size, these wood borers would have remained in the harbor, and the present form of construction would not have obtained. This has not been the fact, however, and 30 years ago the last evidences of the activity of these animals disappeared in all pier construction built either by the City or by others in the Upper Harbor.

In presenting this pier as a type of construction for New York Harbor, the writer took it for granted that it would be understood as applying to piers to be built in the harbor proper, and not for outlying sections nearer the ocean, where, of course, the teredo exists, this form of sea life requiring clear and fresh salt water in order to live. These wood borers have long been driven from the harbor proper. Even 10 years ago, the Department, in approaching the zone of danger (at the end of the Lower Bay) adopted the plan of creosoting all piles, but even in such localities, namely, along the northerly shores of Staten Island, at St. George, and other places where the teredo had been somewhat active, untreated piles which had been in the water for 8 years have been pulled and have shown absolutely no sign of any wood borers.

Before determining to use timber in the South Brooklyn Section, the Department for a number of years made a most exhaustive investigation, with divers, of hundreds of existing piers, bulkheads, and other structures along the water-front, looking for signs of infection by the teredo. The result showed that, although this sea worm had been somewhat active there in years past, it is now practically extinct.

Furthermore, for years past, the Department has been continually repairing the older structures built by the City. In the course of these repairs, the renewal of piles, even in the older structures, is found necessary only at rare intervals in the interior of the piers where they have been protected by the timber deck; though near the sides, where exposure is greater, more extensive repairs are needed. Also, the Department is continually removing old structures, some of them the oldest in New York Harbor, to make way for improvements. In these removals every pile is examined, under orders, for any evidence of the teredo, in order to obtain some idea of the time when it disappeared from that particular locality. In some instances the piles show that they were attacked by the teredo in the olden days, but, probably on account of increasing pollution of the water, it had ceased to exist. Piles removed from structures built within the past 25 years are as good as the day they were driven, and are constantly used again in other work.

Recently, the Department has been removing some of the old Brooklyn ferry houses on the East River, these structures being among the

very oldest on the water-front. In pulling the piles, each was examined with particular care to see if the teredo had made any ravages, but no evidence was found in any case. Mr. Staniford.

The following is a concrete example of the wonderful preservation of these piles and the non-existence of the teredo. When the old Pennsylvania Ferry House, at the foot of Cortlandt Street, one of the oldest structures along the lower water-front near the Battery, was being removed, the writer visited the premises in order to determine whether it would be advisable to use some of the old piles, which happened to be in the right position to take their place as part of the grillage for the concrete retaining wall which was to run under the new ferry house. He found that the piles, cut several feet above low water, were in a remarkably good state of preservation; the foreman, on being told that the piles were as good as the day they were placed, replied, "They are better than the day they were driven." They were subsequently retained and remained in the permanent structure as specimens of absolutely perfect piles, thus saving the cost of placing a number of new ones.

Mr. Snow says:

"There are many examples of concrete construction in sea water in Boston Harbor, and in every instance known to the speaker there has been serious disintegration between high and low tides."

In New York this condition does not obtain in the concrete works produced by the Department of Docks. A few other concrete bulkheads have disintegrated in this way, notably at the Brooklyn Navy Yard, where such a bulkhead, approximately a mile in length, has entirely disintegrated and been removed. The last piece of this concrete wall is now being demolished near the end of the Cob Dock, where absolute disintegration has taken place throughout, extending many feet back from the face, including the front piles, ends of caps, etc.

It is presumed that the Government will replace this wall with a new concrete structure, and then all the old Navy Yard concrete wall will have been reconstructed.

Up to the present time there has been no failure in any part of more than $8\frac{1}{2}$ miles of concrete and granite wall construction, built by the Department of Docks and Ferries, during a period of more than 40 years.

Frank W. Hodgdon, M. Am. Soc. C. E., Chief Engineer of the Massachusetts Board of Harbor and Land Commissioners, writes as follows:*

"Practically all the structures built of concrete in Boston Harbor have been badly disintegrated between high and low-water marks."

* *Engineering Record*, June 10th, 1911, p. 655.

Mr. Staniford.

To this the writer replied as follows:*

"That it will be of interest to your readers is evidenced by the fact that this office is in continual receipt of letters of inquiry from all parts of the world, not only from harbor engineers, but from engineers engaged in the design of bridges in order to ascertain the condition of such work built of concrete in salt water, in view of the failure of such structures throughout the world.

"It certainly is a question concerning which engineers should receive all information possible whereby people at large may receive due consideration in assuming the financial responsibility in future for constructions of this kind which are supposed to be built with a view to permanency.

"I will not attempt to give the history of anything but city construction work in New York Harbor, and the condition of same at the present time. Most of the work done here during the past forty years has been done by the Department of Docks, or what is now known as the Department of Docks and Ferries of the City of New York. During this period the city has been engaged in the construction of a permanent sea-wall, located principally around lower Manhattan, below 80th Street. This has been added to recently by quite extensive construction at North Brother Island, in the Borough of the Bronx, at Whale Creek in the Borough of Brooklyn, and at the Gowanus Section, South Brooklyn.

"This sea-wall in a general way varies in type of construction, according to the character of foundation, but the essential features above the foundation are very similar in all types. Almost every type of bottom is encountered in New York Harbor, while the wall has been built to meet these varying conditions, about twenty-five different modifications having been used thus far in the foundation work to meet the conditions imposed. There are three general types, however; one built upon solid rock, one built upon hard bottom, such as good, stiff clay or compact sand, and one built on soft river mud, forming a wall supported by mud flotation.

"In many parts of the waterfront of Manhattan, for instance, bed-rock is over 200 ft. below the river bottom, overlaid with soft mud. In the rock sections the wall has acquired a height above the rock as much as 50 ft. In other rock sections the wall is founded upon rock that has had to be blasted in order to create a sufficient depth for wharfage in front, and to take off sufficient rock for a stepped-off bottom in order to safely found the wall against the slope of the natural rock.

"In the soft mud bottoms the longest piles are used. In most types requiring pile foundations, the piles are usually cut off at a depth of about 15 ft., below mean low water, and from the top of these piles the wall proper is built.

"In the case of the rock bottom type the wall proper may be considered to commence at the top of the bag foundation which is built immediately on the rock bottom to a proper grade, for receiving the wall proper. From the tops of these pile and concrete bag foundations, the wall is built up to the vicinity of mean low water of concrete blocks, varying according to design from about 20 to about 95 tons

* *Engineering Record*, August 5th, 1911, p. 176.

CONCRETE BLOCKS BUILT AND PLACED IN WALL BY DEPARTMENT OF DOCKS, AND REMOVED BY THE EDISON COMPANY IN THE CONSTRUCTION OF INTAKE TUNNELS.

FIG. 12.—END VIEW.

Mr. Staniford.

in weight. These concrete blocks are moulded in air in mould boxes and are shipped on scows from the yard at which they are fabricated to any point on the waterfront where they are to be used. For handling these blocks we use two derricks, according to weight of block, a 40-ton derrick and a 100-ton derrick.

"Above these blocks the type of construction is generally the same, consisting of four courses of granite facing, of headers and stretchers, dove-tailed into a thick backing of concrete deposited en masse in the rear of the granite, and all carried up to the grade for the granite coping. In several places concrete deposited in situ forming a homogeneous mass with the concrete backing is substituted for granite and carried up to the coping course. This is usually done at points particularly where piers project from the bulkhead, as this portion of the wall is covered by the pier and, therefore, not visible. This type of construction with concrete face, instead of granite face, appears also in the general construction of the Claremont Section, the 116th Street Section, the Gowanus Section in South Brooklyn, the Whale Creek Section in Brooklyn, the Fulton Section on the lower East River, and part of the Old Slip Section on the East River.

"All of this wall construction has been built in the river itself, generally well off from the shore, in salt water, in a tide with an average range of 5 ft., varying in extremes to 8 ft. The tidal and current conditions in most parts of the East River waterfront are so severe that a diver is not able to stand up and work for more than half an hour in slack water, necessitating the construction of temporary breakwater barriers as a protection for the diver and for work against the current.

"The Department of Docks and Ferries, up to the present time, has built about 8½ miles of this river or sea-wall, requiring in its construction in the neighborhood of 6 000 concrete blocks. In the course of years the Department has had many opportunities for examining the condition of this wall in connection with the building of sewers, etc. Up to the present time no disintegration has been discovered that can be attributed to the existence of the structure in salt water. The concrete itself is in an admirable state of preservation, absolutely hard, and is undergoing no regular process of disintegration. In some cases between high and low water marks, where the concrete has been deposited in situ, there are indications of ice abrasions, but nothing whatever to cause any softness or to expect ultimate trouble.

"In some cases there are indications of the effect of wave action or scour on the freshly deposited concrete within the tidal range, due to carelessness in work on the mould boards, creating opportunity for tidal or wave scour, but this trouble does not appear to be progressive after the original scouring action on the freshly deposited concrete, excepting in the case of gravel concrete. It is my opinion that gravel concrete is not a proper material to use en masse (not moulded in air), where it is to be subjected to wave action or tidal effect in the process of depositing.

"Up to the present time the Department has not been obliged to spend much money on repairs to the sea-wall. This wall was built to be permanent, and at the present day all of the exposed concrete, which in the course of a few years may become a little worse from

Mr. Staniford. abrasion than at the present time, can be repaired and brought to its original state with the expenditure of a few hundred dollars.

"The extreme conditions that exist in Boston and that are to be seen in certain parts of this harbor, outside of work done by the city, and, in fact, in all of the various harbors of the world, could not exist and continue in the municipal work of the City of New York under its present financial control and government.

"Concrete harbor works built in other cities under municipal, private or corporate control, as well as constructions in European harbors, were, of course, all built originally as improvements, at great expense, over timber construction which might have been built under ordinary expenditure at a far less cost, and are only permanent investments, according to their behavior; therefore, because of the partial failure or threatened failure of so much concrete work in harbor construction, leading engineers throughout the world are assuming unusually expensive construction in their endeavors to produce permanency, by going to the other extreme and using granite or stone.

"Notwithstanding the failure or partial failure of concrete in the presence of salt water, in certain localities, the fact remains that this sea-wall which has been under construction by the City of New York for 41 years, is at the present time an excellent piece of work and is subject to the same climatic conditions as all cities on the Northern Atlantic Coast with the attendant ice, cold and rain characteristic of this latitude."

With reference to the concrete blocks mentioned by Mr. Betts as having been removed from the bulkhead wall after immersion in the salt water of the harbor for 10 years, Figs. 13 and 14 are submitted. These are from photographs of the blocks after they had been removed from the wall at 38th Street, East River, and placed on the Department Dock at the East 24th Street Yard. These blocks, weighing about 80 tons each, and recorded as Nos. 66 and 82, respectively, were fabricated on June 20th and August 16th, 1902, and were set in the East 38th Street bulkhead wall on July 14th and August 30th, 1902. They were removed from the wall by the Edison Company, in the construction of intake tunnels, on October 31st, 1912.

The abrasions along the top and parts of the bottom edges of these blocks are the result of chiseling, in taking the blocks out of the wall and breaking their contact with the concrete backing and granite which surmounted them. They are in a perfect state of preservation, showing no disintegration, even to the extent of the displacement of a particle. The edges are practically knife-edges, and the sharp-cut ridges along the joint lines of the mould boards show clearly. These blocks will be used in other work of the Dock Department when convenient.

Mr. Taft has presented a design for a permanent concrete dock which no doubt would answer for some localities where the bottom would permit of constructing a foundation such as he recommends. It is novel in many of its features, and has many good points; but the

question of decreasing the thickness of slab in the type of deck now being built by this Department would not be considered here. This is a question that cannot be decided analytically, but must be answered by experience with structures subject to the heavy side shocks which piers receive, together with the shocks from traffic, and from merchandise falling while being handled on the pier. The slab described in the paper has been tried out and its thickness is slightly greater than that used in the original piers; any future change, if ever made, would be to increase it. Mr. Staniford.

It may be interesting to many of the members of the Society to mention that another governing principle with the Dock Department engineers, in evolving a type of pier leading to the use of a reinforced concrete deck, was the elimination of any possible patented process. Municipal contracts in New York must be prepared so as to avoid the use of any patented processes, in order that competitive bids may be received to produce the structure under the design presented. This is not only a barrier, but is troublesome throughout the whole preparation of the contract and while the work is under construction. The Department, therefore, has evolved a type which, at least, has not caused any trouble from this source; it simply calls for a prescribed size of rod and spacing, or their equivalents in other shapes, on which a bid can be made by anybody manufacturing steel for reinforced concrete.

Mr. Taft's type, however, has many good features, and might well be used by private corporations desiring a permanent structure, the writer's only objection to it being the thin slab for heavy traffic. This is not such a serious factor as to detract from its usefulness, as the necessary increase in the thickness of this slab would not add greatly to the cost, although Mr. Taft makes quite a feature of this.

FLOOD FLOWS.*

By Weston E. Fuller, M. Am. Soc. C. E.

With Discussion by Messrs. Arthur E. Morgan, H. V. Hinckley, E. F. Chandler, Allen Hazen, Morris Knowles, Herbert E. Bellamy, E. Kuichling, Robert E. Horton, G. B. Pillsbury, and Weston E. Fuller.

The determination of the magnitude of the maximum flood that may be expected to occur on a river is of importance in many problems connected with engineering works. The problem is a complex one because floods are produced by combinations of a large number of conditions, many of which are themselves variable quantities.

Floods which have occurred on some rivers have been greatly in excess of others on the same river. These great floods come rarely on any one river, but an extraordinary flood occurs on some river every year. A study of their past frequency gives the best indication of what may be expected in the future.

The object of this paper is: 1st, to present a study of the frequency of floods; 2d, to show the relation between the catchment area and the magnitude of the flood; and 3d, to present formulas and tables to serve as an aid to judgment in estimating the probable maximum flood to be expected on a river.

Formulas for problems of this nature should be considered only as convenient and simple means of expressing the data. They serve as a framework on which to arrange the data in an orderly manner, so that they can be better understood and more readily used. The

* Presented at the meeting of October 15th, 1913, held at New Orleans, La.

formulas are of value only when accompanied by clear and concise tables of data. The tables here presented contain coefficients deduced from the data for many streams. These coefficients show the flood-producing capacity of the streams. Coefficients are given for streams in various parts of the country, and should prove of service in selecting coefficients for others for which local data are not available.

The conditions which produce or affect floods may be divided into two classes: First, those which relate to one stream and tend to make all floods on it greater or less than on others; and second, those which are general in their effect, as far as area is concerned, but are variable in time, tending to produce floods of various magnitudes from time to time.

In the first class may be included the following: The prevailing conditions of rainfall; the size, shape, and slope of the catchment area; the character of the soil and vegetation on the catchment area; the physical characteristics of the stream channel; the storage capacity in reservoirs; and many other physical characteristics of the catchment area and the stream itself. Some of these characteristics may be changed in time by the action of the elements or by the works of man; otherwise, their effect on floods may be considered as constant.

In the second class may be included the following: The rate of rainfall; the snow conditions; the temperature conditions; the quantity of water stored in reservoirs, lakes, and ground at the time the flood occurs; the velocity and direction of the storm; the formation of ice dams or other temporary obstructions in the river; and the many other elements which cause one flood to differ from another on the same stream.

No two floods are exactly alike. Two storms of like intensity, velocity, and direction passing over a catchment area may produce different floods. One coming at a time when the water in the ground and in the lakes and reservoirs is low may produce only a moderate flood. A second, coming at a time when the lakes, reservoirs, and ground are filled, may produce a large flood; or, if the second occurs in conjunction with high temperature, when there is a large quantity of snow on the water-shed, a very large flood may occur.

When the great variety of conditions which affect each flood is considered, it will be seen that the number of combinations which may occur is infinite. When many conditions tending to large floods occur coincidently with great rainfall, extraordinary floods are produced.

The chances of such a coincidence may be considered equal for different streams. Clearly, the study of the effect of elements of this class is one in probabilities.

A study based solely on the larger floods would be misleading, as a flood of a size which would be ordinary on one stream may be extraordinary on another stream. It is essential, then, to study each river separately, and to establish some standard which represents a normal flood on that river before the study of the probability of the occurrence of extraordinary floods is undertaken.

The standard selected for this use in this paper is the average yearly flood. By using this average flood, the effect of the variable elements is neutralized to a large extent, so that a direct comparison of one river with another is possible. Also, a comparison of the larger floods with the average flood on the same stream gives a means of determining the frequency with which the former occur.

To give a clearer idea of the scope of the paper and of the methods used, a few definitions, a summary of the more important conclusions, and a statement of the formulas proposed are here given.

Unit of Flood Measurements.—All quantities of flood flow are stated in cubic feet per second.

Twenty-four-Hour Average Flood.—Unless otherwise stated, all floods are on the basis of the average rate of flow for 24 consecutive hours. Most of the data available are on this basis, which is the standard used in publications of the United States Geological Survey.

Maximum Rate of Flood.—As in many engineering problems it is important to know the maximum rate of flow of the flood, a separate study is made to show the relation between the maximum rate of flow and the 24-hour average rate of flow.

Yearly Average Flood.—The yearly average flood of a stream is obtained by selecting the maximum 24-hour average flood for each year and taking the average of these floods.

Frequency of Occurrence of Floods.—By frequency is meant the probable time interval, in years, between the occurrence of floods of approximately the same magnitude.

Nomenclature.—

Q = the greatest average rate of flow for 24 consecutive hours during a period of years, in cubic feet per second;

Q (Max.) = the maximum rate of discharge of a flood, in cubic feet per second;

Q (Ave.) = the average yearly flood, in cubic feet per second;

T = the number of years in the period considered;

A = the catchment area of the river, in square miles;

C = a coefficient which is constant for the river at the point of observation.

Formula Proposed, as Obtained by Plottings of the Existing Data on American Rivers.—

$Q = C\,A^{0.8}\,(1 + 0.8 \log. T)$, in which Q is the largest 24-hour average rate of flow to be expected in a period of T years.

$Q\,(\text{Max.}) = Q\,(1 + 2\,A^{-0.3})$ in which Q (Max.) is the maximum rate of flow to be expected under the same conditions.

SUMMARY OF CONCLUSIONS.

(1) Though flood flows on different rivers vary greatly, some of the characteristics of the rivers affect the floods in substantially the same manner throughout the country; and expressions may be derived which show these effects.

(2) The effect of the size of the catchment area on the flood flows throughout the country is much the same; and this relation between the size of the catchment area and the size of the average yearly flood may be represented approximately by the expression,

$$Q\,(\text{Ave.}) = C\,A^{0.8}$$

such being true only in the case of the 24-hour average rate of flow of the floods.

(3) The relation between the maximum rate of flood flow on a stream in a period of years, and the maximum rate of flow for 24 hours during the same period, may be represented approximately by the expression,

$$Q\,(\text{Max.}) = Q\left(1 + \frac{2}{A^{0.3}}\right) = Q\,(1 + 2\,A^{-0.3}).$$

Table 1 gives the relative size for the maximum rate and the 24-hour average rate for different catchment areas, according to this relation.

(4) On streams throughout the country, floods which are a certain ratio of the average yearly flood occur with much the same frequency, and, on the average, the probable maximum flood in a period of years may be represented by the expression,

$$Q = Q\,(\text{Ave.})\,(1 + 0.8 \log. T).$$

TABLE 1.—RELATION BETWEEN MAXIMUM FLOOD AND AVERAGE 24-HOUR FLOOD.

$$Q\text{ (Max.)} = Q\ (1 + 2\ A^{-0.3}).$$

Catchment area, in square miles. (1)	Ratio of maximum flood to average 24-hour flood. (2)	Catchment area, in square miles. (1)	Ratio of maximum flood to average 24-hour flood. (2)
0.1	5.0	500	1.31
1.0	3.0	1 000	1.25
5.0	2.23	5 000	1.15
10	2.0	10 000	1.12
50	1.62	50 000	1.08
100	1.5	100 000	1.06

Table 2 gives the relative size of flood which may be expected in periods of years, according to the foregoing relation.

TABLE 2.—RELATION BETWEEN FLOOD TO BE EXPECTED IN A SERIES OF YEARS AND THE AVERAGE YEARLY FLOOD.

$$Q = Q\text{ (Ave.) } (1 + 0.8 \log. T).$$

Time, in years. (1)	Ratio of largest flood to average yearly flood. (2)	Time, in years. (1)	Ratio of largest flood to average yearly flood. (2)
1	1.00	50	2.36
5	1.56	100	2.60
10	1.80	500	3.16
25	2.12	1 000	3.40

(5) Coefficients may be obtained for streams by utilizing the foregoing relations to discount the effect of the length of period of observation and the size of the catchment area; these coefficients will serve as a gauge for the flood-producing capacity of the streams; and the difference in value of these coefficients is caused by the various physical characteristics of the river and its catchment area, such as storage, soil conditions, etc., and by the difference in the prevailing rainfall conditions.

Data.—The data available for a study on flood flows consist of records of floods on many streams covering periods of a comparatively few years, of a few continuous records for long periods, and of many scattered data of single great floods. In recent years, the U. S. Geological Survey has obtained observations on a large number of streams, either by its own observers or in conjunction with interested parties.

The Survey has also collected many data from old records. Many State commissions or officers have collected and published data. Some of the best records are those kept by water-power or manufacturing corporations.

Records of the same floods, as quoted in different reports and books, vary frequently. It has been possible sometimes to follow these records to their original source and obtain the most probable value, but undoubtedly many inaccuracies exist. It is believed, however, that in the main the data may be considered as sufficiently reliable to form a basis for a study of this character. At all events, it is the best available at the present time. It is very fortunate that there are a few records which are both accurate and complete, and cover periods of sufficient length to make them of great value. These observations have been made by those who appreciated the value of such records, and to whom accuracy was of the first importance.

The estimates that have been made of flow during great floods on rivers where regular gaugings have not been made are of considerable value as a check on the frequency of occurrence, although many of these estimates are only rough approximations, as an adequate basis for estimate is rarely at hand, especially after the event.

There are probably in existence many other data. The writer has used all that he has at hand, the accuracy of which was not questionable.

The method of rating rivers which is used in this paper, involving as it does simply the observation of the single largest flood in each year, makes it possible to rate a large number. An approximate value for the average flood, and for the coefficient, C, may be obtained from only 5 or 6 years' continuous records.

Effect of the Size of the Catchment Area.—The effect of the size of the catchment area on flood flows is first studied for 24-hour average floods. The method used is to compare the average yearly floods for different rivers. The use of these floods, though it eliminates the effect of the variable conditions involving time, does not in any way eliminate the effect of the constant factors, such as prevailing rainfall conditions, soil conditions, slope, storage, etc. These latter factors are of such importance that floods on streams in one section of the country may be many times larger than those on streams of similar size in another section; and, even in the same section, wide variation

may occur on streams of about the same size. In order to make a comparison which will show the effect of the size of the catchment areas, the streams must be grouped in such a way that the effect of these constant factors will be similar. There are so many of these factors that no grouping can be arranged that will make all of them even approximately equal. On the whole, it seems best to subdivide the country into sections which will have similar conditions as to rainfall and climate, and to rely on the average of a large number of streams to eliminate the effect of the remaining factors. For this purpose the following subdivision by the U. S. Geological Survey may serve as well as any other:

New England States,
Hudson River Basin,
Middle Atlantic States,
South Atlantic States,
Ohio River Basin.

St. Lawrence River Basin,
Hudson Bay,
Upper Mississippi River Basin,
Misscuri River Basin,
Lower Mississippi River Basin.

Western Gulf of Mexico,
Colorado River Basin,
Great Basin,
Southern Pacific Coast,
Northern Pacific Coast.

Tables 12 to 26 contain data on the average yearly floods for the rivers. The data from these tables are plotted on Plates IX, X, and XI.

The rivers in some of these divisions are so much alike in their characteristics that they have been plotted on the same diagram, as follows:

Plate IX. . . . . . {

FLOOD FLOWS.

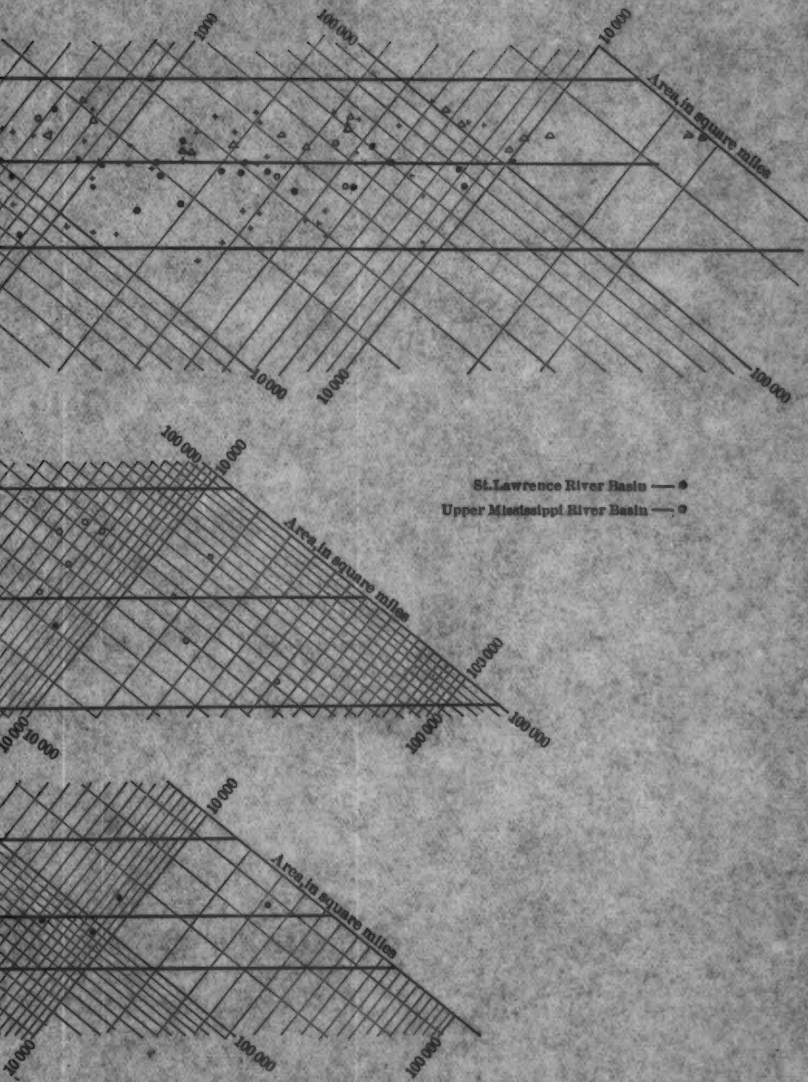

Plate X........	Missouri River Basin and Lower Mississippi River Basin. Western Gulf of Mexico and Colorado River Basin.
Plate XI........	Northern Pacific Coast and Southern Pacific Coast.

The rivers of the Great Basin and Hudson Bay vary so widely in their flood flows that no plottings have been made.

A study of these diagrams, which are on logarithmic scales, shows that, though the plottings cover zones of considerable width, the general slope of these zones is definite, and may be represented by the lines drawn. The data for the rivers on the Eastern Coast are the best, and the diagram for them shows the relation well. The slope of these lines is 0.8, so that it may be stated that the average rate of flood flow during 24 hours varies as the 0.8 power of the catchment area, or Q (Ave.) $= C\,A^{0.8}$.

The plotting for the Lower Mississippi and Missouri Rivers would indicate a slope of less than 0.8. An examination of the characteristics of the rivers on these basins, however, shows that the smaller ones are mainly mountain streams, and the larger ones flow through flat country. There is, therefore, an unbalanced element of difference in the data which may account for the apparent difference in the results.

The general indications do not justify any change in the value of the exponent for different sections; and though the data for some sections are not as satisfactory as for others, it is believed that this relation holds generally throughout the country.

All the plottings made on these diagrams are for a 24-hour average flow, and the formula, Q (Ave.) $= C\,A^{0.8}$, holds for such only. In this it differs from some other formulas proposed, and should not be compared with them.

Maximum Rate of Flood.—For all floods the maximum rate of flow will exceed the average for 24 hours. For the larger streams the rate of run-off will be of considerable magnitude for at least 24 hours, and for small streams a cloud-burst may cause a flood which will run off in a few hours, giving a large maximum rate with only a moderate 24-hour average rate. We should expect then that the maximum rate of flood, as compared with the average rate for 24 hours, will be greater for small than for large rivers.

There are not sufficient data available to admit of a satisfactory independent study of the maximum rates in comparison with the sizes

of the catchment areas. It seems best, therefore, to study the relation between the maximum rate of flow and the 24-hour rate of flow. We are interested more particularly in the maximum rate of the great floods. That is, we want to ascertain the probable maximum rate of flood which is likely to occur in a long period. The greatest maximum rate of flood during a period of years does not necessarily occur during the same flood that gives the maximum 24-hour flood. The larger of the 24-hour floods are usually produced by storms of considerable duration, so that the relative excess of the maximum rate over the 24-hour average rate will not be so great for the large 24-hour floods as it will be for smaller 24-hour floods. In Table 3 is shown the rivers for which both the maximum and the average 24-hour rates were obtained. In some cases these represent different floods, but generally they repre-

sent the same one. These are mainly large floods, but do not necessarily represent the maximum flood on the river. It is probable that the relation, as obtained by the average of the data in Table 3, represents one large enough for use in obtaining the probable maximum rate to be expected in a considerable term of years, although some smaller floods may have a much greater excess of maximum rate over the 24-hour average rate.

The method of obtaining the relation between the two rates of flow is shown on Table 3 and on Plate XII. The ratio of the excess of the maximum rate of flood over the 24-hour average rate to the average rate is plotted to a logarithmic scale in relation to the catchment area, and an average curve is drawn. From this curve may be obtained the relation:

$$\frac{Q\text{ (Max.)} - Q}{Q} = 2\,A^{-0.3} \text{ or } Q\text{ (Max.)} = Q\,(1 + 2\,A^{-0.3}).$$

This should be considered only as an approximate average relation, from which considerable deviations in particular cases are to be expected.

The great rate of flood on the Susquehanna which is shown on the diagram was due to an ice jam, and may be considered as a rare occurrence. It should perhaps be considered as a matter of frequency of flood flows rather than as a relation between the maximum rate and the 24-hour average rate. That is, such an occurrence comes probably only in a long period of time, and during that period larger 24-hour average floods than the one given for this flood would normally occur, so that the relation between the two rates in a considerable period of years would be less than is indicated by this particular flood. Frequently, the ice dam, though it would cause a great flood immediately below the dam, would not increase to a like extent the flood some distance farther down stream, as the temporary storage along the river and in ponds and lakes will take up the water let loose by it and equalize the flow.

Frequency of Occurrence of Floods.—If the data for all the floods that have occurred in a single river for several hundred years were available, a relation could be established showing the average frequency with which floods of any size occur. As such data are not available, it becomes necessary, in order to establish the frequency relation, to utilize data for shorter periods on many rivers. Special

studies were made to see if this relation was similar for different rivers. Although considerable variation occurred for the shorter-term records, these studies showed clearly that a general law could be established. In Tables 12 to 26, the larger floods on many different rivers are compared by using the proposed formula for frequency. An inspection of these tables shows that the values of the coefficient thus obtained are, in most cases, reasonably constant, and are similar to the values obtained by comparison with the average yearly flood, thus indicating that the frequency relation holds for the different rivers.

As rivers follow the same general law, it is allowable to use the data on all the rivers in the same way as those on a single river, provided such data can be put on a common basis. The use of the yearly average flood affords a means of doing this. If the same law holds, the ratio of the larger floods to the yearly average floods should be the same for all rivers for the same period of time. The method of comparing the data and obtaining the frequency is explained in detail later.

As most of the data were obtained during the last 10 or 20 years, objections to this method of analysis may be raised on the score that weather conditions may have been different during other periods in the past, or may be different in the future. Certainly, if weather conditions throughout the country were subject to permanent changes, this objection would be well taken. There is no evidence, however, that this is so. The rivers considered are distributed throughout the United States, so that local conditions should not affect the results. We know that a dry season in one section of the country may occur during the same year as a wet season in another section. We also know that storms which cause great floods on small streams may cause only moderate floods on larger streams, and *vice versa.* Considering these facts, the diversity of the conditions, and the large area over which the rivers are distributed, it seems that periods of 10 years or more give a fair average of the conditions which have existed in the past and will probably exist in the future.

As a check on this frequency relation we have long-term records for a few rivers, which show that the relation holds approximately for these rivers. A few of these records cover a century. A further check is given by the lower diagram on Plate XI, on which the greatest floods of the century are plotted, showing a close relation to the proposed formula.

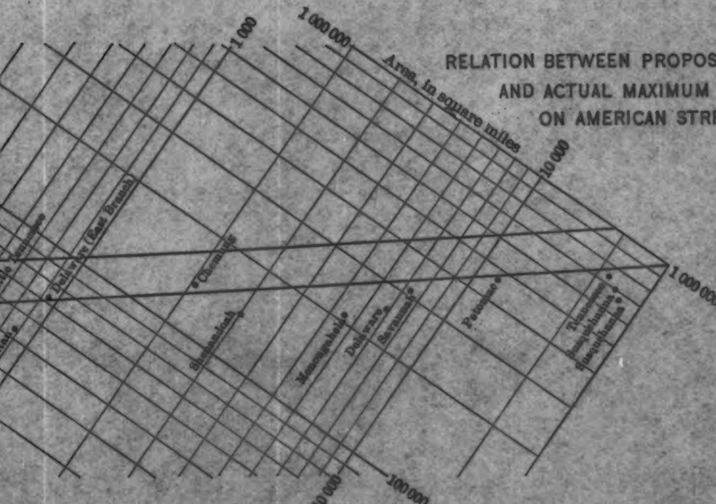
RELATION BETWEEN PROPOSED FORMULA AND ACTUAL MAXIMUM FLOODS ON AMERICAN STREAMS



Method of Determining the Frequency.—As there is some choice as to the flood to be selected in the study for frequency, some matters involving the general method which has been followed are here given.

If we are given a record of floods for a series of years, we may divide it into a number of equal periods of time. Taken independently, the maximum flood in each period might be said to represent the probable flood to be obtained in that period. These maximum floods, however, will vary, and we may select the most probable maximum flood which will occur in a given period by any of the following methods.

First, the average of these maximum floods, which may be called the average maximum flood to be expected in this period of time; second, the one of these maximum floods for which there is one greater for each one less, which may be called the median maximum flood to be expected in the period of time; third, the smallest of these maximum floods, which may be considered as the flood that should be equalled or exceeded in the period of time.

As the yearly floods considered range from a fraction of the average to several times this average, it may be readily seen that there will probably be more floods of less than, than there will be of more than, the average. The average of the maximum floods, then, will exceed the median flood. It is a question which of these two floods better represents the requirements. The average flood is more easily obtained and is more accurate, particularly for short-term records. It is larger, thus leading to safe design. As the study is based on the average yearly floods, it seems better to continue the method and use the average maximum flood. The relation between the foregoing different floods seems to be constant, as is shown in the detailed method given later. It may be stated that it would have been possible to have used the median flood from the start, to have selected the median yearly flood, and to have made the study on that basis. It is believed, however, that, on the whole, the average flood method is the better.

It should be noted that the results are also affected by two other matters. First, only the single largest flood in each year is used. This eliminates all the others during that year, although they may have been greater than the largest flood in other years. If these second and third floods in some years were included in the study, they would tend to give somewhat higher values for the probable flood. On the

other hand, in the method of analysis no attention is paid to the fact that some of the largest floods may come close together. It is assumed that the floods are uniformly distributed over the period, though, in fact, some periods would have two or more floods of the size under consideration while others would not contain any such flood. If this were taken into account, it would tend to reduce somewhat the value of the probable flood to be expected. These errors in methods, if they may be so called, are not of great moment. Generally, it may be said that the flood obtained by the proposed formula is probably somewhat in excess of that which we would expect to get in any one period, but it is the average of the floods in a number of periods of the same length.

General Method.—The general methods of treating the data can be best shown by a specific example. For this purpose, the writer has used Tohickon Creek, the data for which are contained in the reports of the Philadelphia Water Board for 25 years. All the steps leading up to the determination of the average flood and the frequency of occurrence of floods on this stream are shown. In working out the general formula for frequency for all rivers, the same method is followed as here given, the data for all the rivers being collected and used as if they were for one stream. This example then illustrates the entire method of procedure. The first step is to select from the daily records the largest single flood for each year. These are shown in Column 2 of Table 4. The second step is to average all these floods, as is shown at the foot of Column 2. The third step is to select and arrange the floods in order of their magnitude. This is indicated in Table 4, Q_1 representing the largest flood; Q_2 the second; Q_3 the third, etc. The next step is to find the ratio of these larger floods to the average flood. This is shown in Column 3. The next step is to arrange the data so that the frequency may be determined. The methods for doing this are shown in Table 5.

The methods of determining all the three different values for the probable flood to be expected, as previously stated, are here given.

Method of Obtaining Average Maximum Flood to be Expected.—The method of computing the average maximum flood to be expected is shown in Table 5, Part *a*. Column 1 gives the serial number of each flood, in order of size. Column 2 gives the ratio of the flood to the average flood, as taken from Table 4. Column 3 gives the summation

of all the floods equal to or exceeding the flood concerned. Column 4 gives the summation in Column 3 divided by the serial number. Column 5 gives the total number of years in the record divided by the serial number. It is evident, then, that Column 4 represents the average of the floods which occur in the period of years given in Column 5. On the first diagram of Fig. 1 the values in Columns 4 and 5 are plotted on a logarithmic scale for the values of the time (Column 5) and on an ordinary scale for the values of the ratios (Column 4); these plottings are marked *A* on the first diagram of Fig. 1.

Average yearly flood Q (Ave.) $102\,917 \div 25 = 4\,117$.

Median Flood.—The method of obtaining the median maximum flood is shown in Table 5, Part *b*. The second largest flood is here taken as representing the size of that one which will probably come in one-third of the total period. That is, there will be one flood greater, one less, and one equal to it in the three periods. In the

same way, the third flood is taken as the most probable one for a period equal to one-fifth of the total time, and so on. Column 1 gives the serial number from Table 4. Column 2 gives the corresponding ratio; Column 3 gives the time for which this flood is the median, and is obtained by dividing the total time by one less than twice the serial number. Columns 2 and 3 are then plotted as for the first method. These plottings are marked *B* on the first diagram of Fig. 1.

Ratio of Flood to Average Yearly Flood

FIG. 1

Flood to be Equalled or Exceeded.—The method of obtaining the flood to be equalled or exceeded is shown in Table 5, Part *c*. To obtain it we select the least of the maximum floods in the periods. The second flood is taken for one-half of the time, the third for one-third of the time, and the fourth for one-fourth of the time, etc. This means that, considering four periods, there will be three of these which will have a flood larger and one which will have a flood equal to the value which we have selected. The ratios and corresponding periods of time are marked *C* on the first diagram of Fig. 1.

Method of Obtaining Average Relation for Frequency for All Streams.—The method used to obtain the frequency relation for all streams investigated is the same as that illustrated for Tohickon Creek. All the data are used precisely as if they constituted a record for a single river covering a period of time equal to the sum of the length of the records for the individual rivers. In studying the matter of frequency, plottings were made for rivers in many different sections of the country. In this paper only two of these are given; first, that for all the rivers on the Eastern Coast, which represents the best data, covering the greatest length of time; second, the data for all the rivers in the United States for which records of 10 years or more are at hand. The data for the Eastern Coast rivers are given in Table 7 and are plotted on the second diagram of Fig. 1. The frequency relation for these rivers is $Q = Q$ (Ave.) $(1 + 0.75 \log. T)$. The data for all the rivers in the United States with records equal to or exceeding 10 years are given in Table 8 and are plotted on the third diagram of Fig. 1. The relation for these rivers is $Q = Q$ (Ave.) $(1 + 0.83 \log. T)$. For other sections, somewhat different relations were obtained. The difference in these relations is not great. The variation hardly justifies establishing separate values for each section, and a single one is all that is warranted. The expression, $Q = Q$ (Ave.) $(1 + 0.8 \log. T)$ is adopted as the value of the coefficient of log. T as it is between the relation established for the eastern rivers and that for all the rivers.

The relation between the average maximum, the median maximum, and the flood to be equalled or exceeded is shown in Table 6.

In studying the data, a few rivers, located principally in arid and semi-arid regions, were eliminated on account of unusual conditions. In such sections conditions are such that no floods worthy of the name

* Two large floods eliminated, as the record was not continuous. For such cases, where the record includes a few large floods, these are used, after which the computations are adjusted by eliminating the effect of these floods and proceeding as if they had not existed.

occur in some years, though occasionally there is a large one. For such cases the average yearly flood becomes low and the percentage of the maximum flood becomes unduly high. These conditions are quite different from those generally found, and it seems best to exclude such cases. It follows, of course, that the frequency relation here proposed does not hold for such rivers.

USE OF THE FORMULA.

$$Q = C\,A^{0.8}\,(1 + 0.8 \log. T).$$

$$Q\,(\text{Max.}) = Q\,(1 + 2\,A^{-0.3}).$$

Selecting the Value for the Coefficient, C.—Tables 12 to 26 contain values for the coefficient, *C*, for many rivers in the United States. These coefficients are applicable for the river at the station where the floods were observed and for other points on the river where conditions are not materially different. Obviously, the coefficient for a river above large branches or above points where there may be considerable storage may be different from that of the river below. Slopes and other conditions affect the coefficient, and for the river at other points than where the gaugings were made, judgment must be used in its selection. The coefficient for the upper portion of a river may be different from that for the lower portion. The coefficient for the river, however, taken in connection with others for similar rivers, should enable one to select an approximate value for any river in the tables. For streams for which no coefficients are given in the tables, approximate values may be obtained by comparison with rivers having similar characteristics, for which the coefficients are given.

It may be possible to obtain local data as to the height of the ordinary yearly flood, which may give an indication of the value of the coefficient. It may also be possible to obtain records of one or two of the larger floods on the stream, and if one can ascertain the time

when these occurred, the data may be reduced by the formula of frequency to obtain approximate values of C.

Some data of this latter character are contained in Table 28. No attempt has been made to reduce these data to find the value of C, as the information in regard to the period represented is not definite. Local investigation of the conditions might enable one to form a reasonable estimate as to the period of time these floods represent. It is probable that records of other floods on these streams would be available, together with the time of the occurrence, so that approximate values for the coefficients could be established.

The effect on flood flow of such factors as slope of drainage basin, shape of drainage basin, rate of rainfall, etc., have been studied and discussed in a number of papers. For the sake of convenience, and to aid in the selection of the coefficient, C, from the tables, it may be well to summarize briefly the effect of some of these factors, stating generally their effect on the magnitude of the flood.

Storage.—Storage may be in a reservoir, or in the ground. Generally speaking, all storage tends to reduce the size of floods. Rivers on which there are many lakes or reservoirs, or on which there are large sandy areas, generally have low flood flows, as compared with rivers otherwise similar. When the lakes and reservoirs are full, the storage below the overflow is not available for reducing floods. Storage above the overflow, however, is always available, and the quantity stored, as the water rises above the overflow, is certain to reduce to some extent the flood flows in the stream below. In the same way, storage in the ground is more or less available, depending on the condition of the ground-water at that time. The effect of storage above the overflow is to reduce all floods, and the effect of storage in the ground and that below the overflow is rather to make large floods of less frequent occurrence.

The temporary storage above the overflow is the most important for natural reservoirs, such as lakes and ponds. Where reservoirs are controlled and used for power purposes, or for water supply, the storage below the overflow may be important; but as these reservoirs may be filled when the larger floods come, dependence cannot be placed on such storage.

It is evident that this storage will affect the floods resulting from different types of storms in different ways. A storm producing a

long-continued flood will fill the available storage while the supply is still at a high rate, so that the maximum rate for the flood may be nearly as great as would have occurred without the existence of the reservoir. On the other hand, a flood from a short, sharp storm will be greatly reduced by storage, because, before the storage is filled, the supply will be much less.

In order to ascertain what effect this storage may have on the maximum rate of flood, a few specific cases were considered.

TYPES OF FLOOD FLOWS CONSIDERED

FOR SHOWING EFFECT OF STORAGE ON A STREAM

OF 1 SQ. MILE CATCHMENT AREA

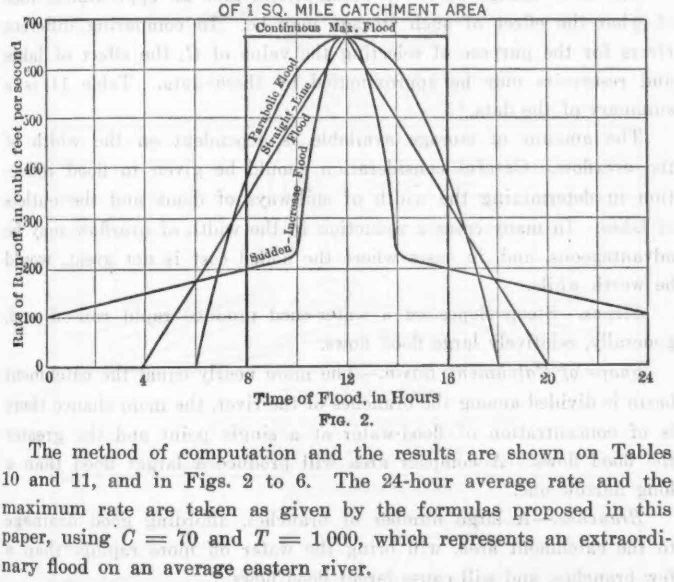

FIG. 2.

The method of computation and the results are shown on Tables 10 and 11, and in Figs. 2 to 6. The 24-hour average rate and the maximum rate are taken as given by the formulas proposed in this paper, using $C = 70$ and $T = 1\,000$, which represents an extraordinary flood on an average eastern river.

Four different types of flood flows are considered, as shown on Fig. 2. These cover in a general way the more common floods. The ideal type, called the Continuous Maximum, gives the minimum limit for the effect of storage. In these computations it is assumed that the reservoir sides are vertical and that the overflow is from a weir with vertical sides, from which the rate of overflow varies as the $\frac{3}{2}$ power of the height of the water passing over the weir.

Figs. 3, 4, and 5 show the effect of different amounts of storage for the assumed conditions. Table 10 contains a summary of the results of the computations for different cases.

Fig. 6 shows a plotting of the data in Table 10.

From these tables and diagrams the effect of this storage for the assumed conditions is apparent. The study is made for the effect on comparatively small catchment areas for which the flood at a high rate would usually not last more than 24 hours. For larger rivers, for which long-continued storms are common, the study does not apply.

The data, though based on assumptions, give an approximate idea of what the effect of such storage may be. In comparing different rivers for the purpose of selecting the value of C, the effect of lakes and reservoirs may be approximated by these data. Table 11 is a summary of the data.

The amount of storage available is dependent on the width of the overflow. Careful consideration should be given to flood reduction in determining the width of spillways of dams and the outlets of lakes. In many cases a reduction in the width of overflow may be advantageous, and, in cases where the added cost is not great, would be worth while.

Slopes.—Steep slopes on a water-shed produce rapid run-off and, generally, relatively large flood flows.

Shape of Catchment Basin.—The more nearly equal the catchment basin is divided among the branches of the river, the more chance there is of concentration of flood-water at a single point and the greater the flood flows. A compact area will produce a larger flood than a long narrow one.

Branches.—A large number of branches, affording good drainage to the catchment area, will bring the water off more rapidly than a few branches, and will cause larger flood flows.

Condition of River-Bed.—The condition of the river-bed itself is an important factor. A river-bed which has frequent points of congestion which tend to hold back the water and provide temporary storage will have smaller relative flood flows than one with a smooth even bed which allows the water to run off rapidly. The hydraulic properties of the river channel, such as the hydraulic radius and the coefficient of roughness, affect the rapidity of the run-off, and thus

FIG. 4.

the magnitude of the flood. The better the hydraulic properties, the greater the relative flood flow. The chances of damage by the flood in such case, however, may be less.

Rainfall.—The annual rate of rainfall has been embodied in some flood formulas. This may be misleading, as it is the intensity and duration of the rainfall during or immediately preceding the flood that is the principal factor. Until more information is available on the rainfall conditions, as to intensity and duration, it is probable that this element is better left to judgment as to its effect on the coefficients of streams.

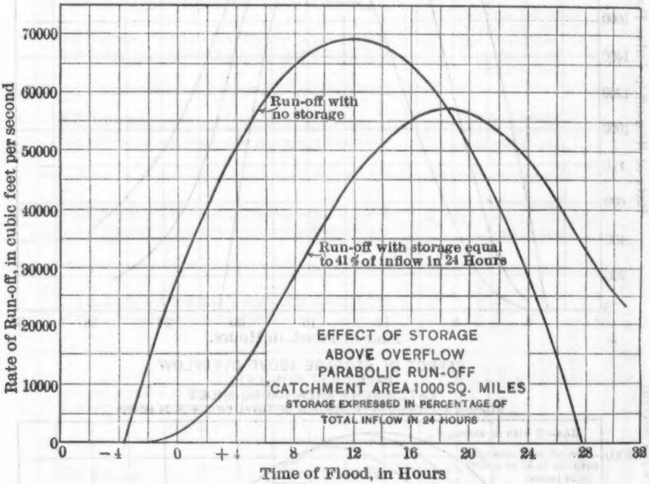

FIG. 5.

The effects of many of these factors are not the same for different floods. In some cases characteristics which would reduce the flood under average conditions tend to increase it for particular conditions. For example, it is entirely possible that storage will hold back the water on some of the branches of a river until such a time as greater quantities of water are coming from other and larger branches, thus producing a greater flood on the main stream than would have occurred if there had been no storage and the first branch had run off rapidly. Such a condition, however, is an exception, and the foregoing may be said to hold in average cases.

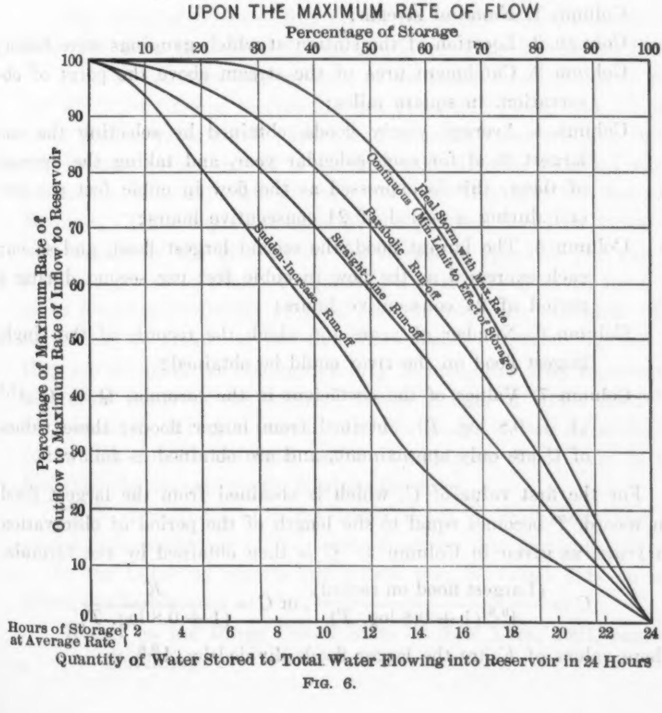

Fig. 6.

Values for the Coefficient, C, in the Formula, $Q = C\,A^{0.8}\ (1 + 0.8 \log. T)$.

Tables 12 to 26 contain flood data on the rivers in the United States for which the records could be obtained with sufficient completeness to give an approximation of the coefficient, C, in each case. Rivers for which observations are being taken at present, with records covering 4 years or more, are included, although, for these short-time periods, the value of the coefficient may be considerably in error, and should be adjusted when more complete records become available.

Each table contains a group of rivers corresponding to the classification made by the U. S. Geological Survey, and the arrangement of the rivers is similar to that given in the more recent papers of the Survey, in order that reference can readily be made thereto.

The tables contain the following data:

Column 1. Name of stream;

Column 2. Location of the station at which gaugings were taken;

Column 3. Catchment area of the stream above the point of observation, in square miles;

Column 4. Average yearly floods, obtained by selecting the one largest flood for each calendar year, and taking the average of these; this is expressed as the flow in cubic feet per second during a period of 24 consecutive hours;

Column 5. The largest flood, the second largest flood, and so on; each expressed as the flow in cubic feet per second during a period of 24 consecutive hours;

Column 6. Number of years for which the records of the single largest flood on the river could be obtained;

Column 7. Values of the coefficient in the formula, $Q = C\,A^{0.8}$ $(1 + 0.8 \log. T)$, obtained from larger floods; these values of C are only approximate, and are obtained as follows:

For the first value of C, which is obtained from the largest flood on record, T becomes equal to the length of the period of observation in years, as given in Column 6. C is then obtained by the formula,

$$C = \frac{\text{(Largest flood on record)}}{A^{0.8}\,(1 + 0.8 \log. T)},\ \text{or}\ C = \frac{K}{(1 + 0.8 \log. T)},$$

where values of K are the larger floods divided by $A^{0.8}$.

For the second value of C, Q becomes the average of the largest and the second largest floods; and the value of T becomes one-half of the period of observation, or

$$C = \frac{K + K_2}{1 + 0.8 \log. \left(\frac{1}{2}T\right)}.$$

For the third value of C, Q becomes the average of the three largest floods, and T becomes one-third the period of observation, or

$$C = \frac{K + K_2 + K_3}{1 + 0.8 \log. \left(\frac{1}{3}T\right)}.$$

Other values of C are obtained in a similar manner.

Column 8. Value of coefficient, C, as obtained from the average yearly flood; $C = \frac{Q\ (\text{Ave.})}{A^{0.8}}$.

This value of C, depending on all the yearly floods, is more accurate than those in Column 7, and should generally be selected for use.

Table 27 contains data on some of the larger single floods on rivers for which continuous records are not at hand. These data are taken from various reports and papers, and in many cases are only roughly approximate estimates. It is assumed that the flow recorded was the maximum rate, although in some instances this may not have been the case. These represent some of the greatest floods on record, but not necessarily the greatest on the stream in question for any considerable period of time. Frequently, a stream is observed for a year or so for some particular purpose, and the floods are recorded. These floods may be greater or less than the normal, but, from the fact that they are recorded, the assumption may be made that they represent the maximum floods on the stream. Tables of data of single floods may be misleading for this reason. In this study, it was in some cases found that flows taken from tables of maximum floods were actually less than the average yearly flood on the river.

Table 27 includes only the larger floods of this kind; and they probably represent one of the larger floods on that particular river.

In the following reports and papers may be found data on many rivers not here given:

Report on the Barge Canal, State of New York, 1901, page 844, Kuichling.

Hydrology of the State of New York, Rafter.

Geological Survey of New Jersey, 1904, Vermeule.

Reports of Pennsylvania Water Supply Commission.

Reports of New York State Water Supply Commission.

Reports of Maine State Water Storage Commission.

United States Geological Survey, Water Supply Paper No. 147, page 184.

United States Geological Survey, Water Supply Paper No. 162, "Destructive Floods."

Selecting the Value of T, in Design.—Floods have occurred on some rivers during the last 20 years which, normally, would be repeated in not less than 1 000 years. If works are to provide for floods equal to the greatest that have been observed, a value of T of at least 1 000 should be used. Such a flood or a greater one may occur on any river at any time, but it is not likely to come soon on any particular stream. It must be remembered that the use of $T = 1\,000$ does not mean that the corresponding flood will come at the end of 1 000 years, but that the chances are even that it will occur at some time during a period of 1 000 years. It means, also, that the chances are 1 to 1 000 that it will occur in any one year, or 1 to 100 that it will occur in 10 years, or 1 to 10 that it will occur in a century.

The selection of the proper value of T then becomes a question of what chance we can afford to take. In the design of a spillway of an earth dam, the failure of which would cause great damage, a large value of T should be used. The design of a temporary dam for construction purposes, the failure of which would mean only small damage, would call for the use of a comparatively small value of T.

The decision as to the value of T to be selected should depend on considerations of the first cost of the construction required to provide for it, together with the probable damage in case the flood exceeds the quantity provided for. The added cost due to using a larger value of T may be regarded as insurance against loss. Obviously, if insurance is costly, as compared to the risk, less should be taken. Consideration of possible loss of life and property, together with loss of business, or loss of a water supply for a city, and other factors, must be taken into account in deciding on the proper value of T. Possible increased damage in the future, due to building up of sections below the dam, or unusual difficulties in reconstruction, must be considered.

Although the selection of the proper value of T must be a matter of engineering judgment, the following method will give the economic value: Estimate the probable amount necessary to make good all damage caused by the flood exceeding the allowed amount. Multiply this by the probability of the flood occurring in one year. The product

is the annual value of the flood risk. Estimate the first cost of the works necessary to provide for floods of a magnitude corresponding to these values for T. Multiply this by the going rate of interest. The product is the annual interest charge. Select the value of T for which the sum of the annual value of the flood risk and the annual interest charge is a minimum.

Comparison with Other Flood Formulas.

Table 29 is a list of some other formulas for obtaining the maximum flood flow. These formulas are of different forms, and contain many different terms. Some are intended only for use over a limited section, and others are for more general use. In order to make any comparison, it is necessary to assume values for the variable terms. The values assumed are intended to suit average conditions in the eastern portion of the United States. Three of the formulas were derived for such conditions, and the others were for European and Indian conditions. For the purpose of comparison, data on some of the larger floods on foreign streams are given in Table 30. On Plate XIII the formulas in Table 29 are plotted, together with three curves representing the formula proposed in this paper. An examination of this diagram shows that formulas vary widely. This is to

be expected, as the data on which they are based are very different. On the whole, it may be said that the formula proposed in this paper gives relatively higher values of the flood flow for very small and very large catchment areas. Probably the reason for this is that the formula was derived from average floods, and many, if not all, of the others were derived from maximum floods. There are numerous records for medium-sized streams, but not for very small or very large ones. It is to be expected, under these conditions, that the highest relative maximum floods will be found on rivers of medium size. There are comparatively few very large rivers in Europe, and their number in America is limited. Although there are many small streams, damage from flood on them is not usually great, and records of their floods are comparatively few. More records of small streams are probably available on European than on American rivers.

Some of the largest floods on foreign and American streams are plotted on Plate XIII. The largest of these are on streams in India and Saxony. The upper curve, representing the proposed formula,

with $C = 250$ and $T = 1\,000$, covers all except two of these floods. There is no record of any American flood as large as these, although the record of the Siletz River, covering a 3-year period, includes one of great magnitude; the maximum rate is not stated, but the 24-hour average rate is relatively greater than that of any flood recorded on any other American stream. It is stated by the U. S. Geological Survey that this stream is typical of those in that section of Oregon, and it seems probable that floods there equal or exceed those on foreign rivers. It is also probable that other floods for which no records are available have exceeded any of those recorded.

On the lower diagram of Plate XI are plotted the larger floods on the rivers in the eastern part of the United States. The two curves drawn to represent the formula, with $C = 100$, $T = 1\,000$, and $C = 100$, $T = 50$, cover these great floods well. These may be considered as extraordinary floods on streams which usually give large floods. These few floods represent the largest ones on many rivers during the last 50 or 100 years, so that some of them may be those

which would normally occur in very long periods, and others may be floods on rivers having coefficients greater than 100, which would normally occur in shorter periods. When it is considered that the formula was obtained from data independent of these floods, the agreement is noticeably close, and serves as a valuable check on the formulas here proposed.

Comparison with Flows in Sewers.—In Table 28 is given a comparison of the proposed formula with that of McMath for obtaining the flow in sewers, $Q = C R \sqrt[5]{S A^4}$. In making the comparison, a period of 20 years is assumed, as it seems that sewers liberally designed should flow at full capacity at least once during such a period. For the proposed formula, C is taken as 65, which is the

average coefficient for eastern rivers. For the McMath formula, values are assumed as follows: $C = 0.50$, $R = 2.75$ in.; $S = 10$ to 30. These values seem reasonable when it is considered that, during a period of 20 years, an unusually heavy rainfall would probably come on frozen or well-saturated ground, for which the percentage of run-off would be as great as, or greater than, it would be from a 50% impervious area in a city. Table 28 indicates that the flows for small catchment areas, as obtained by the proposed formula, are fairly consistent with sewer experience.

By grouping rivers according to their values of C, and investigating the rainfall conditions, storage, slopes, amount of sandy area, etc., for these different groups, it seems probable that much valuable information could be obtained with the data now available.

The writer feels that the method of rating and comparing rivers by using the average yearly floods affords a means of obtaining valuable information on many rivers, with a comparatively small amount of labor, and hopes that in the future the maximum flood for each year will be observed for many more rivers. It is also to be hoped that

records of both the 24-hour average rate and the maximum rate of flow will be made for our larger floods, and that for all records of floods it will be clearly stated as to which rate it refers. In this study it was difficult, in many cases, to distinguish between the two.

Acknowledgments.—As far as the writer knows, the first suggestion of the use of the element of time in a formula for flood flows was made by Allen Hazen, M. Am. Soc. C. E., in a memorandum written by him in 1910. This memorandum contained a study of maximum floods on some eastern rivers, and suggested a formula of a nature similar to the one proposed in this paper. Mr. Hazen has followed closely the progress of the study which is here presented, and to him the writer is indebted for many valuable suggestions.

The late Richard Hazen, Jun. Am. Soc. C. E., was associated with the writer in the earlier and essential portions of this study, and it was the intention that he should write the paper jointly with the writer. As this is now impossible, the writer can but acknowledge his indebtedness and pay tribute to the great amount of able work done by Mr. Richard Hazen in the preparation of this paper.

The writer also wishes to acknowledge his indebtedness to those who have furnished data for the paper. Free use has been made of

Part 14 of the Report on Water Supply by Emil Kuichling, pp. 844 to 851.

No. (1)	Author of formula. (2)	Formula. (3)	Notes. (4)
1	Fanning	$Q = 200\ A^{\frac{5}{6}}$	Adapted to rivers in New England, etc. A = catchment area, in square miles.
4	Dickens	$Q = 500\ A^{\frac{3}{4}}$	Adapted to rivers in Central Provinces, India. This formula is also given with the following coefficients: 200, 825, 1 200, and 2 200; each one is applicable to a different part of India; 500 is here taken as a representative value.
8	Ganguillet	$Q = \dfrac{1\,421\ A}{3.11 + \sqrt{A}}$	Adapted to Swiss streams.
9	Italian	$Q = \dfrac{1\,819\ A}{0.311 + \sqrt{A}}$	Adapted to streams in Northern Italy.
10	Italian	$Q = \dfrac{2\,600\ A}{0.311 + \sqrt{A}}$	Adapted to small brooks in Northern Italy.
11	O'Connell	$Q = \sqrt{458\ (640\ A + 4.58)} - 45.8$	Adapted to small districts.
12	Dredge or Burge	$Q = 1\,300\ \dfrac{A}{L^{\frac{2}{3}}}$	If A is taken as a rectangle having dimensions L and $\frac{L}{2}$, $A = \frac{L^2}{2}$, and the formula reduces to $Q = 1\,030\ A^{\frac{2}{3}}$.
13	Craig	$Q = 440\ n\ B$ hyp. log. $\dfrac{8\ L^2}{B}$	n = coefficient for the drainage basin, assumed as 1.16; L = extreme length of drainage basin; B = average width of drainage basin. If L is taken as being equal to $2\ B$, the formula reduces to $Q = 365\ \sqrt{A}$ hyp. log. $(22.7\sqrt{A})$.
14	Bürkli-Ziegler	$Q = C_1\ R_1 \left(\dfrac{S_1}{A}\right)^{\frac{1}{4}} A$	Assume for $C_1 = 70$ $R_1 = 3$ in. of rain per hour. $S_1 = 4$ (slope per 1 000) Formula reduces to $Q = 296\ A^{\frac{3}{4}}$.

TABLE 29.—(*Continued.*)

No. (1)	Author of formula. (2)	Formula. (3)	Notes. (4)
15	Possenti	$Q = C_2 \frac{R_2}{L_1}\left(A_2 + \frac{A_1}{3}\right)$	L = length of water-shed. Assume for $C_2 = 1\,010$ (Kuichling), $R_2 =$ 6 in. rain in 24 hours, $L_1 = \sqrt{2A}$ as in (12), $A_2 = \frac{A}{2}$ Hilly part of water-shed, $A_1 = \frac{A}{2}$ Level part of water-shed, Formula reduced to $Q = 2\,856\, A^{\frac{1}{2}}$.
16	Cramer	$Q = \frac{C_3 R_3 m\ A\ (S_2)^{\frac{1}{3}}}{9 + (0.0658\ m\ R_3\ A)^{\frac{1}{2}}}$	Reduced by Kuichling, for conditions on Mohawk River, to $Q = \frac{80.6}{1 + 0.1\,347\,(A)^{\frac{1}{2}}} A$
17	Lauterburg	$Q = A\left[\frac{615}{6 + 0.00259\,A} + 0.53\right]$	
	Kuichling	$Q = \left(\frac{44\,000}{A + 170} + 20\right) A$	(1) for flood exceeded occasionally.
		$Q = \left(\frac{127\,000}{A + 370} + 7.4\right) A$	(2) for flood exceeded rarely.
	E. C. Murphy and others	$Q = \left[\frac{46\,790}{A + 320} + 15\right] A$	Formula taken from U. S. Geological Survey, Water Supply and Irrigation Paper No. 147.

DISCUSSION

Mr. Morgan.

ARTHUR E. MORGAN, M. AM. SOC. C. E. (by letter).—Mr. Fuller's paper suggests several very profitable fields of inquiry, and is sure to stimulate further investigations that will be of definite value.

One of the fundamental assumptions is that weather conditions throughout the United States are not subject to "permanent changes." It is also assumed that climatic conditions which will produce maximum storms do not occur over the country as a whole during any given year, but that storm conditions are more or less local. An examination of the monthly and yearly precipitations at rainfall-recording stations in all parts of the United States seems to indicate the general accuracy of this assumption for the last 100 years. However, certain notable facts stand out which lead one to question its accuracy for the interior part of the United States.

For instance, in 1844, the largest flood ever recorded occurred in the Red River, through Texas and Arkansas, this river having a drainage area of about 50 000 sq. miles. During the same year the greatest flood on record occurred in the Kaw River, at Kansas City, where the drainage area is 35 000 sq. miles, and the same year produced the greatest flood in a century and a quarter on the Mississippi River, at St. Louis, and the greatest floods on record in the Missouri and Illinois Rivers. The areas over which the floods of 1844 were the greatest on record, are comparable to the total area of France and Germany. Again, in 1903, the greatest flood since 1844 occurred in the Kaw River, at Kansas City, in the Mississippi River, at St. Louis, and in numerous other streams throughout the Central States. As far north as central Minnesota, the heaviest rainfall ever recorded occurred at the same time. Also, in 1903, floods, among the greatest on record for those streams, occurred on the Verde River, in Arizona, the Colorado River, the Raritan and the Delaware, in New Jersey, Cape Fear River, in North Carolina, the Alabama River, in Alabama, the Monongahela River, and on various other streams, from South Carolina to Oregon. Although there is no definite evidence that periods of maximum floods will occur over the entire country at the same time at long intervals, it appears that so little is known about the facts of the case that this assumption is far from being proven for long periods under conditions existing in the central part of the United States. It is possible that certain seasons at long intervals are subject to unusual storm disturbances resulting in floods, though the average yearly or even monthly rainfall may not be above the normal for the country as a whole.

Mr. Fuller assumes that the relation between the average annual flood and the maximum possible flood is the same for largely different

Mr. Morgan.

sections of the country, and the same for the United States as for Europe. He draws attention to the fact that in the arid regions of the United States rainfall and floods are very erratic, and that, though several years may pass without a flood, very large floods may occur.

Although the data are very meager, the writer believes that the climatic conditions which cause this tendency are not limited to the arid regions, but extend to a greater or less degree over the entire United States between the Appalachian and Rocky Mountains, which is the region in which he is particularly acquainted with flood flows.

For instance, careful calculations of flow on the Miami River, at Dayton, Ohio, have recently been made. A gauging station has been maintained in good order at this point for 20 years. The average annual flood for this period is approximately 32 000 cu. ft. per sec. from an area of about 2 500 sq. miles. According to the formula proposed by Mr. Fuller, the maximum flood for a century should be about 2.9 times the average annual flood, or about 85 000 cu. ft. per sec. According to fairly dependable approximations, this flood flow has been largely exceeded four times in the last 107 years. According to Mr. Fuller's formula, the maximum possible flood in 1 000 years would be about 3.9 times the average annual flood, whereas, according to very careful calculations of flow, it appears that the flood of March, 1913, was about 8 times the average annual flood. It may be that climatic conditions show a greater range of variation west of the Appalachian Mountains than east of that range, or in Europe, from which most of the long-time records referred to by Mr. Fuller were secured.

Another assumption by Mr. Fuller is that the same ratio between average annual floods and maximum possible floods exists for streams, regardless of the size of the drainage area. The writer believes that general experience will fail to uphold this assumption. It is known that small drainage areas are subject to very extreme precipitations, and that the most extreme of these precipitations are always local.

For instance, there is the case of the flood on Devil's Creek, in Iowa, which occurred in 1905. Rough estimates of this flow made by the U. S. Geological Survey* indicate that, from an area of 143 sq. miles, the run-off was about 1 300 sec-ft. per sq. mile. From rainfall records at the surrounding stations it appears that from 10 to 12 in. fell on the water-shed, the greater part of it in 12 hours.

Although little dependence can be placed on such estimates of run-off as are recorded for this flood, the rain which fell was sufficient to produce an average 24-hour run-off of probably not less than 200 sec-ft. per sq. mile, or 8 in. from the entire water-shed. This is in a region where the average annual rainfall is about 35 in. and where the annual average maximum rainfall for 24 hours will not exceed about 2 in.,

* Reported in Water Supply and Irrigation Paper No. 162.

Mr. Morgan. the heavier storms coming during the summer when run-off from small rainfalls is light. It is safe to assume that during the flood of 1905 the maximum 24-hour run-off for this territory was not less than 10 times the average annual flood. This extreme case is given simply to illustrate the fact that the range of flood run-off is far greater for small than for large areas.

Similarly, during the flood of March, 1913, in the Miami Valley, certain tributaries with drainage areas of 50 or 100 sq. miles indicate a maximum run-off of at least 400 sec-ft. per sq. mile, which is probably at least ten times the average annual flood. On large water-sheds of 10 000 sq. miles or more, excessive rainfall in one part of the water-shed is usually balanced by lack of rainfall in another part, and the ratio between the average annual flood and the maximum possible flood must be less than for small areas.

When alluvial streams overflow, sand and silt are deposited along the banks up to within 2 or 3 ft. of the surface of the overflow. Along the lower Mississippi and the Red Rivers, in Texas and Arkansas, and the Arkansas River, in Arkansas, there is no evidence of such silt and sand being deposited at elevations very much above those of recent floods. The conclusion is that during recent centuries there have not been floods in which the stage of water was very much above that of recent ones. The only points at which such comparisons can be made safely are along the abandoned loops and cut-offs in the rivers, where the banks have not caved in. On the contrary, on small streams evidence of very different conditions is found. It is fairly common experience, along streams with water-sheds of from 10 to 500 sq. miles, especially in the northern and mid-western States, to find deposits of gravel very evidently placed by flood-water at elevations very much above the elevation of any recorded flood.

The inference is that all the interior part of the United States is subject to very rare local floods of very great intensity, comparable, perhaps, to the one already referred to on Devil's Creek, and that the run-off of such maximum possible floods may be ten times as great as the average annual flood, instead of three or four times as great, as indicated by Mr. Fuller's formula. The suggestion is that, in determining the relation between average annual floods and the maximum possible flood, the extent of the drainage area is an important factor.

The data do not indicate the extent to which flood records have been examined, in the preparation of the paper, but the flood flows on foreign streams outlined in Table 30 would not, it seems, furnish a reasonable basis for the acceptance of such a formula as suggested. For instance, of the floods for which the date is given, more than one-third occurred in 1887 and more than one-half of them in a period of 7 years.

This paper is valuable in that it suggests pointedly that there is a definite relation between the average annual flood on any stream and the maximum possible flood for that stream, and in suggesting that, to a certain extent, short-time records for many streams will serve the same purpose as long-time records for a single stream. Mr. Morgan.

When one considers the number of assumptions which must be made in the use of the formula for determining the maximum possible flood, it would seem that in some cases it might be better to estimate the maximum possible flood by what might be called the rational method, that is, by determining from the basis of experience and the maximum rainfall to be expected, the relation of rainfall to run-off under the conditions which would exist in an assumed case, considering the elements of topography, shape of the drainage basin, direction of storms, season of the year, etc.

There is just one other point that should be mentioned. Mr. Fuller states very clearly that there are two kinds of variables to be met in flood flow: one class varies with different rivers, and includes topography, soil conditions, etc.; the other class of variables, including possibilities of rainfall, weather, temperature, etc., may be alike for many streams, but vary as to time. A statement has been made by the author, which does not appear in the paper; this indicates to the writer the value of his work, but also possibly, the danger of feeling too secure by an improper placing of the burden on those two elements. For instance, if we use his formula, we must assume a value for C, that is, a value representing the variable conditions with regard to water-sheds, etc. If C is made to fit the case, the formula can be made to fit any particular river or flood, but unless we know how that factor, C, was determined, we do not know whether the formula fits any particular case accidentally, or whether C has been determined properly. Mr. Fuller has mentioned one particular river in which he assumed the coefficient, C, to be 100, that is the Miami above Dayton, Ohio. The difference in elevation there between the top of the water-shed and the river valley is seldom more than 200 ft., as compared with mountain streams where the variation may be 1 000 ft.; and the soil formation is variable, being gravelly in some cases. At the time of examining this paper, the writer discussed it with other engineers in his office and came to the conclusion that one could not assume for that valley any higher factor for C than 50. The point is, that in plotting various storms, unless the engineer is thoroughly familiar with the variable factor, C, on one water-shed, as compared with the value of that factor on other water-sheds, he does not know the extent to which the intensity of flood flow is determined by the variable, C, which is constant for that water-shed, and to what extent it is determined by the time variable, including rainfall, season, temperature, etc.

Mr. Hinckley.

H. V. Hinckley, M. Am. Soc. C. E. (by letter).—In addressing the Oklahoma Engineering Society, on December 27th, 1911, the writer said:

"Some of us are perhaps not aware that a 20 or 30-year record of high water, minimum or maximum flow, or rainfall, may often be of comparatively little value. It seems to be a fairly well established rule that it takes fully 50 years to complete an engineering meteorological cycle. This was illustrated, for example, at Topeka, Kans. When the Melan Bridge was built over the Kansas River in 1897, the City Engineer's records for 25 years showed a maximum rise of 15 ft. from L. W. to H. W., and the oldest inhabitant, who claimed that he had seen the river go clear out of its banks and flood the entire valley prior to 1850, was deemed to be in his dotage and untrustworthy. In 1903, however, the recorded variation of 15 ft. between low and high water was changed to 28 ft.; asphalt pavements were 6 ft. under water; the oldest inhabitant was vindicated, and the river proved what every one should have known—that the high-water mark, in an alluvial valley which has been built up by sediment dropped by the floods, is necessarily higher than the ground surface of the valley—regardless of the records of the City Engineer's office."

While these remarks bear out, in a general way, the author's conclusions, the writer acknowledges that his 50-year "meteorological cycle" is subject to amendment.

Tables 1 and 2 give, at a glance, an idea of what may be reasonably expected, and, from this time forward, the Profession will be able to act more intelligently in the design of waterways and storage reservoirs. The writer has been collecting data in regard to maximum rainfall for 30 years, and the two subjects together are an interesting study.

There are plenty of bridges and spillways which may stand up under 1.80 times the annual flood, but will go out when 3.40 times the annual flood comes.

The writer, having kept a record of intensity of rainfall in the United States for the past forty years, offers a table and a diagram (Fig. 7) of the same, and begs the author's pardon for injecting "Rainfall" into "Flood Flows," and for applying his table backward for constructing three of the curves on the diagram.

TABLE 31.

By Author's Table 2.		Rainfall intensity ratios.
Years.	Flood ratios.	
50	2.36	1.00
10	1.80	0.76
5	1.56	0.66
1	1.00	0.42

Mr. Hinckley.

The maximum rates of rainfall from which the 50-year curve was constructed several years ago (without any attempt to evolve an equation for it), are as follows: 14 min., 16.90 in. per hour; 3 hours, 5.33 in. per hour; 11 hours, 2.70 in. per hour.

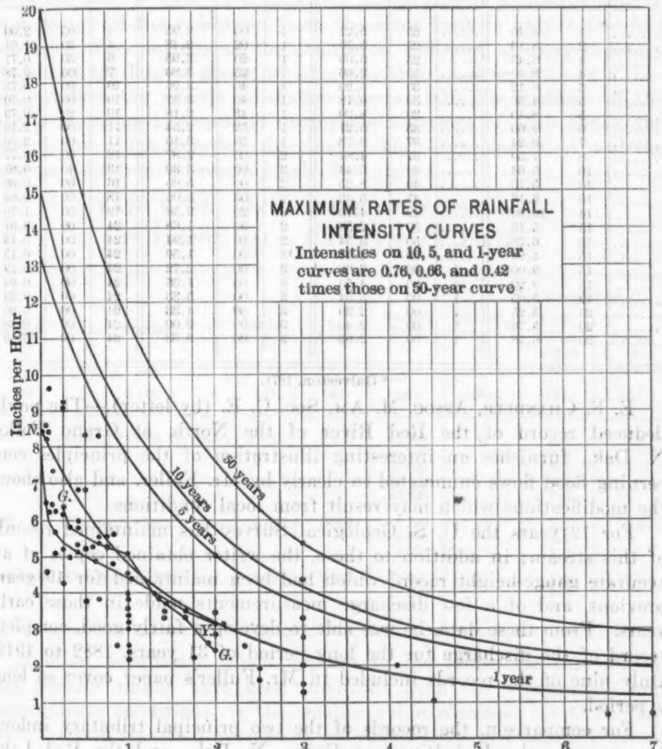

FIG. 7.

It is interesting to note how closely the resulting 1-year curve fits two downpours which have been reported, from New York for October 16th, 1913, and Galveston, for October 22d, 1913, which are designated on Fig. 13 as "N-Y." and "G-G.", respectively.

The author has given us a valuable paper which has propounded to every hydraulic engineer the question: "For how many years will your works stand?"

Mr. Hinckley.

* Galveston, 1871.

Mr. Chandler.

E. F. CHANDLER, ASSOC. M. AM. SOC. C. E. (by letter).—The newly deduced record of the Red River of the North, at Grand Forks, N. Dak., furnishes an interesting illustration of the principles concerning flood flows enunciated so clearly by Mr. Fuller, and also shows the modifications which may result from local conditions.

For 12 years the U. S. Geological Survey has maintained records of this stream; in addition to these, the writer obtained copies of an accurate gauge-height record which had been maintained for 19 years previous, and of a few discharge measurements made in those early years. From these data, he was able to develop a fairly good, complete record of the discharge for the long period of 31 years, 1882 to 1912. Only nine of the records included in Mr. Fuller's paper cover so long a period.

For comparison, the records of the two principal tributary inflowing streams, the Red River, at Fargo, N. Dak., and the Red Lake River, at Crookston, Minn. (which have been observed for 11 and 10 years, respectively), may be considered at the same time. The complete records to date for these stations are shown in Table 33, and might be included in Table 18.

The largest floods did not occur in the same years at these stations, notwithstanding the fact that the latter two are tributary to the first; therefore, all three records may be considered.

In each case, the largest flood was less than that which would be given by the logarithmic formula, on the basis of the median floods.

It seems that this might reasonably have been expected from the topographic characteristics of the Red River Valley, the river and all its main tributaries flowing through remarkably level prairies, usually in channels only a few hundred feet wide and from 10 to 40 ft. below the prairie level. On each side the prairie is almost as smooth as a floor, and the rise away from the river bank is only a few feet per mile. The capacity of the channel is sufficient to carry ordinary floods, but the largest floods, which occur only once or twice in a decade, overflow the prairie in shallow sheets; thus the regimen of the stream is changed essentially during the extremes of such floods, the rate of flow much retarded, the time of high stage increased, and the extreme maximum correspondingly diminished. Mr. Chandler.

Another peculiarity which appears in the tables for this region, and perhaps might have been predicted from the topographic and meteorologic conditions, is the smaller value obtained for C in Column 8 (from the flood average of all years) than in Column 7 (from the largest floods). The Red River Valley is near the "semi-arid" region, and the river separates a prairie State from one largely forested. At one margin of the drainage area, the mean annual rainfall is about 16 in., at the other margin 24 in.; the long-period mean annual run-off is about 1 in. at one side and 4 in. at the other. Therefore, in a region where evaporation consumes almost the whole of the precipitation, and the run-off is so small a remainder, after any season of deficient rainfall, the run-off becomes much less even than the normal, and then remains comparatively steady until the ground storage is replenished by surplus rainfall, and at such times it is little affected

Mr. Chandler.

by ordinary rainstorms. Thus, though the greatest recorded flow at each of these stations is ten or twelve times the long-period mean run-off, there are many years when there is no noticeable flood, and three or four years out of every ten when the largest flood of the year is less than three times the mean discharge. As a result, Q (Ave.), the average of the annual floods, gives a smaller coefficient than that obtained from the larger floods individually.

It is probably the same cause, namely, the small maximum discharge of some years, which gives rise to a different logarithmic factor (in a formula deduced only from the streams of this region) than that deduced by Mr. Fuller from the average of streams scattered through the whole country. Instead of the factor, 0.80 log. T, in the formula, $Q = C\,A^{0.8}\,(1 + 0.80 \log. T)$, the largest flood at each of these three stations would give 0.95 log. T, 1.12 log. T, and 0.90 log. T. In this region, as mentioned previously, the greatest floods do not seem to be as great in comparison with those of secondary magnitude as is normal in other regions; if, therefore, we omit a few of the largest from consideration, the following floods would give factors from 1.10 log. T to 1.30 log. T.

Mr. Fuller states that the rivers of the Hudson Bay drainage varied so widely among themselves that no logarithmic plottings of them were published. The Red River Valley portion of the basin, however, including these three records and numerous other shorter or less accurate records, shows fair uniformity. As Mr. Fuller explains, in some cases local conditions may be expected to modify the application of the formula or to change it to some extent, and such seems to be the case here. The importance of this case would not be great enough to justify this addition to the discussion, were it not for the length of the record—31 years. We see illustrated how useless or erroneous it would be to attempt to deduce figures concerning the flow of an unknown stream where no actual measurements had been made in the region; but, on the other hand, by using the records as a basis for small necessary modifications, the principles enunciated by Mr. Fuller seem, in general, to apply in this region also, and to furnish excellent starting points for more detailed studies.

Mr. Hazen.

ALLEN HAZEN, M. AM. SOC. C. E. (by letter).—This is a most important paper, because, as far as the writer knows, it is the first attempt to apply the principles of probabilities to the flood problem.

The writer has followed the author's work in detail, and believes that his methods are sound. As time goes on, data covering longer periods and more streams may change some of the numerical values; but the underlying idea of treating the recurrence of floods as a matter of probabilities, to be determined by an examination of the records of many streams, will stand.

Mr. Hazen.

When the writer first took up the study of this problem, several years ago, he believed that it would be safer to use as a basis the records of a few streams which covered long periods, where knowledge of flood flows had been obtained from records of the height of water over the crests of substantial dams above the influence of back-water, and where there could be no question as to the accuracy of the results. On the basis of a limited quantity of selected data, tentative values were reached. The author afterward extended the investigation to include short-term records of many more streams; but the numerical values resulting from this broader study were fully in accord with those first obtained by the writer from the small quantity of selected data.

Taking into account the many elements of error which exist or can be imagined to exist in stream gaugings, and especially the fact that estimates for extreme floods in many or most cases are based on extrapolations from rating curves, often at some distance above the highest stage for which gaugings have actually been made, the writer would feel disposed, in case they differed, to attach quite as much importance to the results obtained from his first study. As the more extended studies presented by the author are entirely in accord with the writer's earlier ones, this question does not require discussion, and the writer feels confidence in the general accuracy of the results.

In another paper to be presented to the Society, the writer has described a graphical method of representing data of the same general character as those used by the author, based on the probability curve, or, as it is otherwise called, the normal law of error. A new kind of cross-section paper is made, in which the spacing of the lines in one direction is computed from tables of the probability curve, so that figures representing the summation of that curve plotted on it fall in a straight line.

From a study of the author's data, it is clear that the relation between flood flows and the normal law of error is such that this probability paper could have been used for his study, had it been available. Its use might have facilitated some of the work, but there is no reason to think that it would have changed to a significant extent any of his conclusions. In fact, the paper the author has used for his study corresponds so closely with that part of the probability paper in which most of his data would fall, that the differences would not have been important in the graphical method.

The figures for maximum flood flows of the same stream through a series of years clearly bear a relation to the normal law of error, but they do not follow it exactly. When plotted on probability paper they form what is called a skew curve. The variations downward are more numerous than the variations upward, but are smaller in magnitude.

Mr. Hazen. It is interesting to note that if the logarithms of the numbers representing the several floods are used instead of the numbers themselves, the agreement with the normal law of error is closer. In other words, the variations up and down from the mean follow a geometric rather than an arithmetical ratio.

If the records of the floods of a number of streams were available for very long terms, it would be possible to find a "standard variation" and a "coefficient of variation" from the records of each stream, which would be an index of the degree of variability to be expected in its floods, and indirectly of the size of the floods to be anticipated. There is no reason to suppose that the coefficients of variation in flood flows for different streams would be the same. However, short-term data are not sufficient to determine the coefficient of variation with the requisite degree of accuracy to make this comparison; and the assumption tacitly made by Mr. Fuller, that the coefficient of variation of all the streams in one geographical group will be the same, may be found to be nearly in accordance with the facts. At any rate, the data now available are not sufficient to justify a further classification.

The constants found in the proposed flood-flow formula deduced for rivers in different parts of the United States throw some light on this point. If the coefficients of variation in flood flows in different parts of the country differed considerably, there would be differences in these constants. The smallness of the differences found by the author indicates a surprising degree of uniformity in flood conditions for a large part of the country, and this uniformity by districts may be taken as an indication of the probable absence of wide variations among different streams in the same district.

To attempt to secure actual coefficients from the data at hand, and to compare with one another streams having records no longer than are now available, is like attempting to find the probability of a house burning down from the records of single houses.

In the practical application of the author's formula, the value of the coefficient to be multiplied by $A^{0.8}$ to produce the average annual flood, is a matter of the first importance. In only a limited number of cases will it be possible to base such estimates on actual gaugings of the stream for which estimate is to be made. In a majority of cases, it will be necessary to depend on the records of other streams more or less similarly situated.

On Fig. 8, an outline map of the United States, the coefficients for the streams, for which Mr. Fuller presents data, have been plotted. This map serves conveniently to show what data are available at this time. It is seen that there are large parts of the United States which are not covered at all, and others which are covered most inadequately. In forming judgment as to the probable value of the

Mr. Hazen.

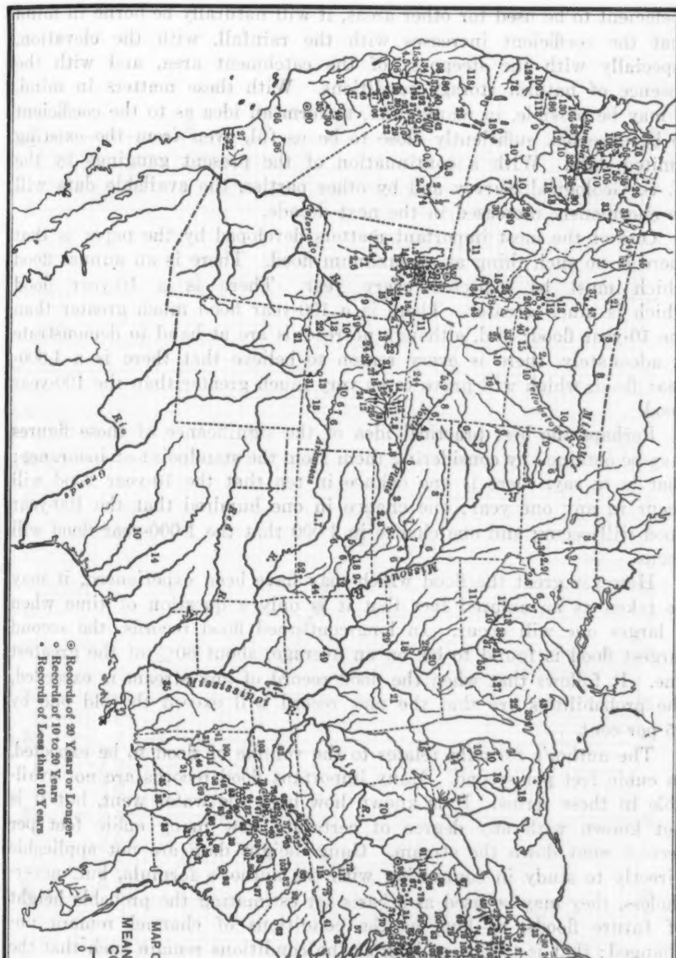

FIG. 8.

Mr. Hazen. coefficient to be used for other areas, it will naturally be borne in mind that the coefficient increases with the rainfall, with the elevation, especially with the steepness of the catchment area, and with the absence of natural storage conditions. With these matters in mind, it may be possible, in many cases, to form an idea as to the coefficient to be expected, sufficiently close to be useful, even from the existing limited data. With a continuation of the present gaugings by the U. S. Geological Survey and by other parties, the available data will be enormously increased in the next decade.

One of the most important matters developed by the paper is that there is no such thing as a maximum flood. There is an annual flood which must be expected every year. There is a 10-year flood which is much greater. There is a 100-year flood much greater than the 10-year flood; and, although no records are at hand to demonstrate it adequately, there is every reason to believe that there is a 1 000-year flood, which will prove to be very much greater than the 100-year flood.

Perhaps the best practical idea of the significance of these figures may be obtained by considering them from the standpoint of insurance; that is to say, there is one chance in ten that the 10-year flood will occur in any one year; one chance in one hundred that the 100-year flood will occur; and one chance in 1 000 that the 1 000-year flood will occur.

However great the flood which may have been experienced, it may be taken as an assured fact that it is only a question of time when a larger one will occur. In long-continued flood records, the second largest flood is found to be, on an average, about 80% of the greatest one. It follows that when the flood record of any stream is exceeded, the probabilities are that the new record will exceed the old one by 25 per cent.

The author's formula relates to the volume of flood to be expected, in cubic feet per second. Many important flood records are not available in these terms. It is known how high the water went, but it is not known with any degree of certainty how many cubic feet per second went down the stream. Gauge-height data are not applicable directly to study in connection with the author's formula, but, nevertheless, they may be used as a basis for estimating the probable height of future floods, as long as the conditions of channel remain unchanged; that is to say, as long as the conditions remain such that the same volume of discharge may be expected to produce the same or nearly the same height of water. Within this limit, as the quantity of discharge, or some function of it, follows approximately the normal law of error, and as the height of water is a function of the quantity of discharge, it follows that the height of water, or some function of it, will follow approximately the normal law of error; and, with constant

Mr. Hazen.

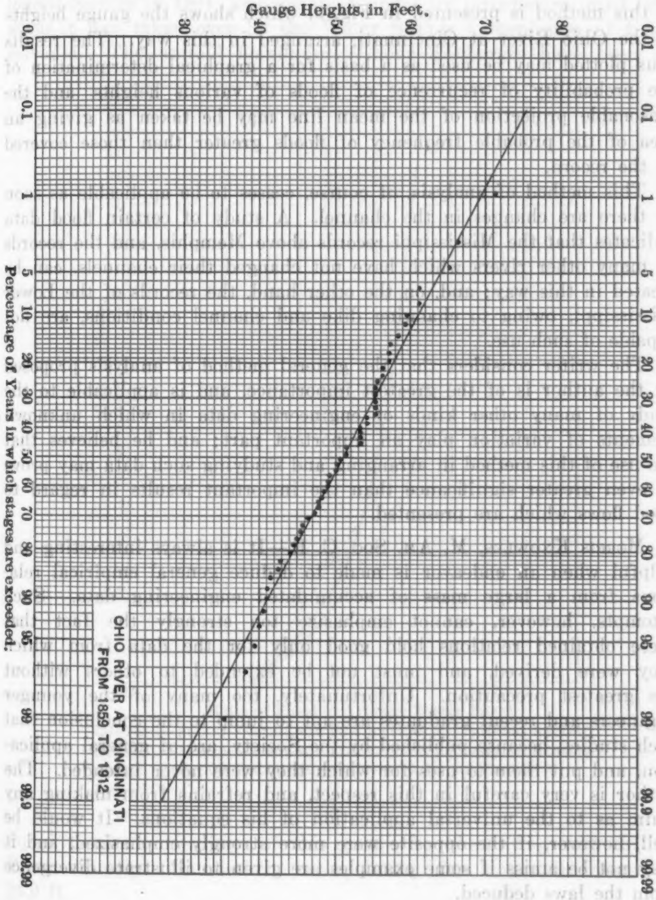

FIG. 9.

Mr. Hazen. channel conditions, the records of gauge heights for a term of years may be arranged in the order of magnitude and plotted, as the author has plotted his flood data, on logarithmic paper, or as the writer would prefer, on the probability paper previously described. An illustration of this method is presented in Fig. 9, which shows the gauge heights of the Ohio River at Cincinnati, arranged in this way. The results thus plotted may be used as a basis for a graphical determination of the probability of recurrence of floods of various heights, and the reasonable projection of the mean line may be taken as giving an idea of the probable frequency of floods greater than those covered by the record.

This method of analysis, of course, ceases to be applicable as soon as there are changes in the channel. A study of certain flood data indicates that the Mississippi records above Memphis, and the records of many other rivers which have not changed their channels, can be treated in this way; and, on the other hand, the records of the Lower Mississippi, owing to changing dike and channel conditions, are not capable of such use.

The writer considers that the general method of analysis proposed by the author is of the greatest importance, and is applicable to the study of many other kinds of engineering data in which unknown elements of variation play an important part; and he believes that the use of this method in arranging and studying such data may prove of even greater significance than the important results in regard to flood flows which are presented.

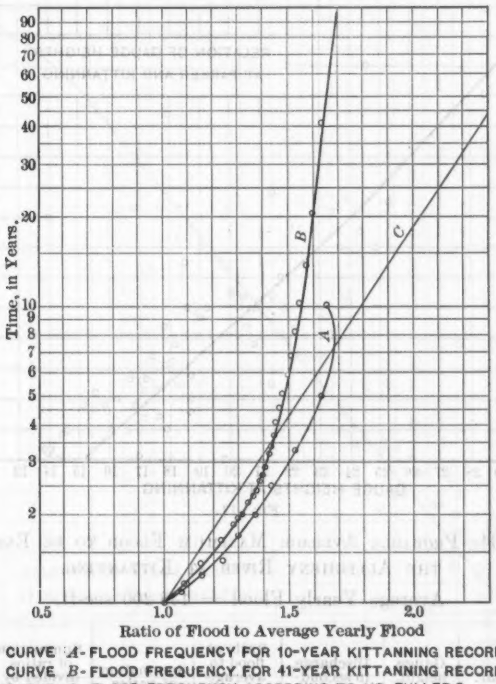
Mr. Knowles. Morris Knowles, M. Am. Soc. C. E.—It is always interesting and helpful when an endeavor is made to deduce general empirical relations from a large mass of accumulated engineering data. Such attempts, however, cannot emphasize too strongly the fact that these obtained relations hold good only for the data from which they were derived, and must not be extended to others without the greatest precaution. Unfortunately, too many of the younger engineers and recent graduates are apt to jump to the conclusion that such studies, because published by the Society, are of general application, and put them to uses for which they were never intended. The author is very careful in this respect, and refrains from making any claim as to the universal application of his equations. It would be well, however, if the opposite were more strongly emphasized, and it may not be amiss if some examples are given to illustrate divergence from the laws deduced.

Point is given to these remarks by the fact that, at about the time this paper was published, the speaker was interested in investigating the magnitude and frequency of floods on the Allegheny River at Kittanning, Pa., and was led to check up the relation between average

Mr. Knowles.

and maximum floods as shown by the records with that indicated by the author. The results may be of some interest.

Gaugings of the Allegheny River at Kittanning are now available for 10 years. The gauge was established by the United States Geological Survey in 1904, and remained under its jurisdiction until 1907, when it was taken over by the Water Supply Commission of Pennsylvania. The annual maximum 24-hour discharges have been de-



CURVE *A*- FLOOD FREQUENCY FOR 10-YEAR KITTANNING RECORD

CURVE *C*- FLOOD FREQUENCY ACCORDING TO MR. FULLER'S EQUATION.

FIG. 10.

duced from the readings of this gauge, by the rating table of the Water Supply Commission, extrapolating for stages in excess of 25.0 ft.

Following the methods used by the author in compiling Table 5, the results shown in Table 34 are obtained.

Plotting the values in Columns 7 and 8 on logarithmic paper, as was done for Curve *A* on Fig. 1, gives the curve, *A*, on Fig. 10. This

Mr. Knowles.

is interesting in that it is not a straight line, as is the case for all the rivers for which plots were made by the author.

With the idea of studying the effect of increasing the period of observation, an attempt was made to complete the Kittanning record for a total of 41 years, by studying the relation of recorded gauge readings at Kittanning with those at Freeport and Parker. The gauge

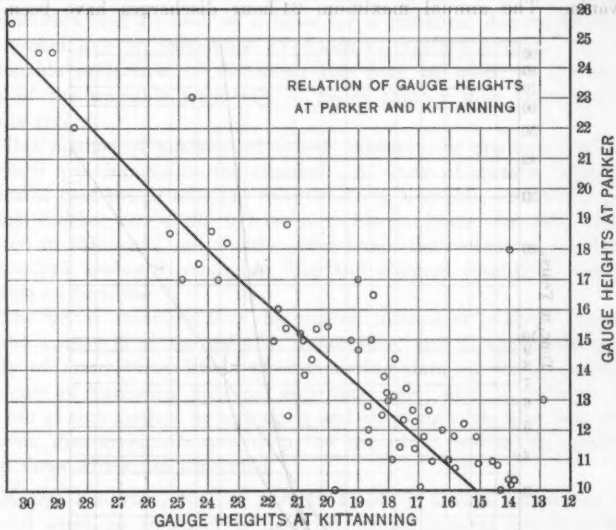

FIG. 11.

TABLE 34—PROBABLE AVERAGE MAXIMUM FLOOD TO BE EXPECTED IN THE ALLEGHENY RIVER AT KITTANNING.

Average Yearly Flood = 148 200 sec-ft.

No. of flood, in order of magnitude. (1)	Year. (2)	Gauge height, in feet. (3)	Discharge, in second-feet. (4)	Ratio of flood to average yearly flood. (5)	Summation of ratios. (6)	Summation of ratios divided by number of flood. (7)	Time, in years. (8)
1	1913	29.5	247 500	1.67	1.67	1.67	10
2	1905	28.2	234 200	1.58	3.25	1.63	5
3	1908	24.3	190 200	1.30	4.55	1.52	3.3
4	1912	23.0	172 000	1.16	5.71	1.43	2.5
5	1909	22.8	168 800	1.14	6.85	1.37	2.0
6	1910	20.8	139 100	0.94	7.79	1.30	1.7
7	1911	19.1	118 000	0.79	8.58	1.23	1.4
8	1907	15.9	86 500	0.59	9.17	1.15	1.25
9	1906	14.0	69 100	0.47	9.64	1.07	1.1
10	1904	12.4	56 100	0.38	10.02	1.00	1.0

at Freeport, 26 miles below Kittanning, was established in 1873, and that at Parker, 39 miles above Kittanning, in 1884. As Freeport is at the mouth of the Kiskiminetas River, one of the largest tributaries of the Allegheny, and as no important tributaries enter at Parker or between Parker and Kittanning, it was thought that a more constant relation might be expected between the gauges at Kittanning and Parker, than between those at Kittanning and Freeport. Mr. Knowles.

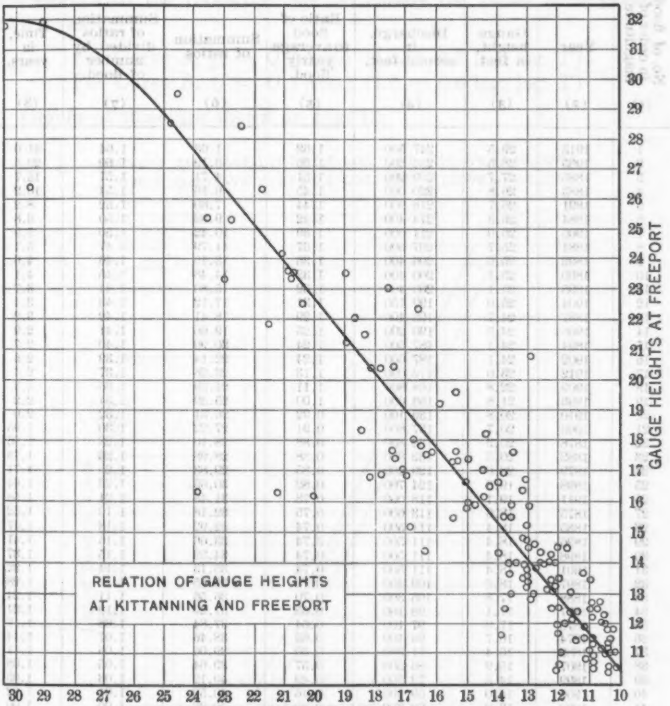

FIG. 12.

All gauge readings of 10 ft. or more at Kittanning since 1904, therefore, were plotted, with the corresponding gauge readings at Parker and Freeport, as shown in Figs. 11 and 12. Estimated Kittanning gauge heights were taken from the Freeport curve for the period, 1873-84, and from the Parker curve for 1884-1904. In plotting the Freeport-Kittanning curve, all points representing local floods in the Kiskiminetas River were given less weight.

Mr. Knowles.

Estimating the corresponding discharges from the same rating curve, and proceeding as before, gives the results shown in Table 35.

TABLE 35.—PROBABLE AVERAGE MAXIMUM FLOOD TO BE EXPECTED IN THE ALLEGHENY RIVER AT KITTANNING, 1873-1913, INCLUSIVE.

Average Yearly Flood = 151 300 sec-ft.

No. of flood in order of magnitude. (1)	Year. (2)	Gauge height, in feet. (3)	Discharge, in second-feet. (4)	Ratio of flood to average yearly flood. (5)	Summation of ratios. (6)	Summation of ratios divided by number of flood. (7)	Time, in years. (8)

40	1906	14.0	69 100	0.46	40.58	1.01	1.02
41	1880	13.0	60 800	0.40	40.98	1.00	1.00
			6 202 850	Average = 151 300			

Plotting Columns 7 and 8 of Table 35 on logarithmic paper gives Curve B on Fig. 10. This, also, is not a straight line, and though its upper portion is nearly straight, the line does not pass through the point ($R = 1$, $T = 1$) as would be required by the equation:

$$R = 1 + 0.8 \log. T.$$

Curve *C*, Fig. 10, shows the author's equation, and indicates that its use would yield results too large, or on the side of safety, as compared with the computed expectancies, for all periods in excess of 5 or 6 years. Mr. Knowles.

It may not be without interest to add that several attempts were made to obtain an equation which would fit Curves *A* and *B*, and it was found that the following checked closely for values of T greater than 2 years:

$$\text{For Curve } A,\ Q = Q\ (\text{Ave.})\ (1.7 + 0.6 \text{ log. log. } T)$$
$$\text{For Curve } B,\ Q = Q\ (\text{Ave.})\ (1.6 + 0.6 \text{ log. log. } T)$$

Graphs of these are shown on Fig. 13.

CURVE *A*. $Q=Q$(AVE.) (1.7+0.6 LOG. LOG. T)10-YEAR RECORD.
CURVE *B*. $Q=Q$(AVE.) (1.6+0.6 LOG. LOG. T)41-YEAR RECORD.

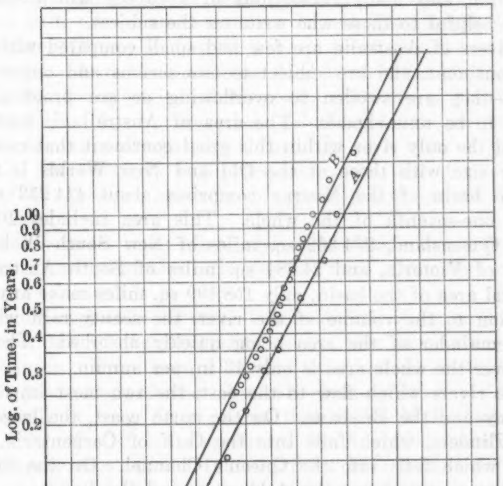

FIG. 13.

It should be noted in passing that the average annual flood computed by the speaker for the 10-year record at Kittanning, or for any conservative 7 years of that record, is substantially greater than that given by the author for the Allegheny River at Kittanning in Table 16. No doubt this is due to the use of a different rating curve in connection with the gaugings.

Mr. Bellamy.

HERBERT E. BELLAMY, ASSOC. M. AM. SOC. C. E. (by letter).—This paper is most interesting and well worthy of a place in the *Transactions* of the Society. The problems associated with the great rivers of America, and the great forces of Nature brought into operation by the enormous rainfalls of that country, spread over great catchment areas, are subjects of much interest to engineers. The writer is sure that those resident in Australia especially will be very thankful to the author for his valuable paper, and also for the lucid manner in which he has presented it. From a careful perusal, it would seem, to those studying the question of the discharge of rivers in flood times, that the tabulated statements submitted by Mr. Fuller, comparing one river with another, supply information which has long been needed. This comparison is of great value. It suggests a method which is simple, and at the same time possesses certain elements of mathematical precision and many indications of accuracy which will be exceedingly helpful to those who write on the subject.

The rivers of Australia are few and small compared with the size of the Continent, and are subject to two serious and opposite disadvantages—they are swollen to overflowing or are practically dried up so as to be unnavigable. The area of Australia is 2 950 000 sq. miles, and the only river within this great continent that can be compared for size with those of the Old and New Worlds is the Murray. The basin of the Murray comprises about 414 253 sq. miles, or about one-seventh of the whole. This area includes 104 525 sq. miles of Queensland, 234 362 sq. miles of New South Wales, 50 979 sq. miles of Victoria, and 24 384 sq. miles of South Australia; but, of the total area of the basin, only 158 499 sq. miles make any effective contribution to the volume of the river, the scanty rain which falls on the remainder of the area being quickly absorbed. The average rainfall over the whole area is only 13 in. per annum.

Of the rivers which flow to the east, the two most important are the Fitzroy and the Brisbane. On the north coast, the largest rivers are the Flinders, which falls into the Gulf of Carpentaria, and the Victoria, which falls into the Queen's Channel. On the west coast, the best-known rivers are the Ashburton and the Swan.

The misfortune of Australia, as regards rainfall, is that the mountain ranges, which act as condensers, lie so near the east coast. The result is that the narrow coastal plain gets more rain than it needs, and, when the rain-bearing winds from the Pacific have crossed the mountains and table-lands into the interior, the great heat there dissipates the clouds and does not permit them to condense into rain.

In attempting to form a rule for flood discharges for Australian rivers, it will be found that there are as many exceptions as there are rivers, and further that the flood discharge in each river varies according to the precise locality in which it is measured. The writer

considers that the question of the fresh-water floods of Australian rivers in relation to the areas and physical features of their basins is one of those multiform problems which can only be solved by special attention to the peculiar circumstances of each particular case. One of the chief wants experienced by the water engineer in Australia arises from the scantiness of reliable data regarding the occasional floods to which the rivers especially, and parts of the country generally, are subject. There is probably much valuable information in the hands of a few engineers now engaged on public works throughout the country, but, except in one or two cases, it has never been collected for reference. In any case there is great difficulty in securing reliable evidence of the levels attained by great floods which occurred more than 40 or 50 years ago. This difficulty has been found by the writer on several occasions when desiring to fix permanent levels for new pumping stations to be constructed on the banks of rivers in connection with town water supplies. In one case, for Rockhampton, on the Fitzroy River, he deemed it advisable to fix the engine-house floor level 3 ft. above the maximum flood level, although flood records were available for a period of 47 years. Records of the heights of various floods in this river have been tabulated by the writer.* Mr. Bellamy.

On the eastern coast the flood discharge of a river is greater per square mile for relatively small drainage areas than for larger ones, because of the greater intensity of precipitation on the former in time of storm.

The author states that: "In studying the data, a few rivers, located principally in arid and semi-arid regions, were eliminated on account of unusual conditions."

It is more especially to these latter conditions, in so far as they pertain to a few of the Australian rivers, that the writer wishes to direct attention. From even a cursory examination of Table 36, and the brief description of the physical characteristics of Australian rivers, it will at once be apparent that it would be impossible to establish a set of coefficients applicable for Australian conditions.

The Murray rises, as the Indi, in Pilot Mountain, 5 000 ft. above sea level, and, receiving a large number of tributary mountain torrents fed by the snows of the Muniong and Bogong Ranges, flows swiftly down from the table-land on the lower plain, falling 4 500 ft. in its first 300 miles. Toward Albury it is joined by the Mitta and Kiewa, and, between Albury and Wentworth, the affluents of the Murray are the Ovens, Goulburn, Campaspe, and Loddon from the south, and the Murrumbidgee and Darling from the north. The fall of the river from Albury downward varies from 9 to 4 in. per mile. From Wentworth, however, to Lake Alexandrina, the fall is only 3 in. per mile. Lake Alexandrina has an area of 288 sq. miles, and the outlet

* *Minutes of Proceedings*, Inst. C. E., Vol. CLXIII.

Mr. Bellamy. for the Murray is through the Goolwa and Coorong Channels, which unite at Mundoo Island, and form one channel to the sea. The mouth of the Murray resembles many of the Australian bar-bound coastal rivers, and proposals have been made from time to time to make it navigable; but, on account of the formidable and costly difficulties to be encountered, nothing has yet been done.

The Goulburn River is the largest and most important Victorian tributary of the Murray. This river, which flows into the Murray at a point 880 miles from Morgan, and 676 miles from the South Australian boundary, for the twelve years ending with 1903, inclusive, had a maximum discharge of 37%, a minimum of 16%, and a mean of 23%, of the discharge at Morgan. The mean monthly discharge was from 30 to 70% in 1884, and from 21 to 62% in 1887, of that of the Murray at Echuca, which is 10 miles below the junction. The description of the Upper Murray is, in many respects, applicable to this river. It takes its rise in the Dividing Range, near Wood's Point, where the summits reach an elevation of 5 000 ft. The drainage area is about 9 000 sq. miles, about 1 500 sq. miles being in mountainous country of considerable elevation. This portion of the catchment area is rocky and precipitous, and a large proportion of the rainfall is discharged. The winter volume of the river is large, and the melting snows maintain the discharge far into the summer. About 5 200 sq. miles of the total catchment are effective, the remainder being non-contributing. The term, Goulburn Valley, is limited, by popular usage, to the plain which extends from the Town of Murchison northward to the Murray.

The Lachlan River possesses a reputation for irregularity of flow which is, perhaps, not paralleled by any other river in Australia. As illustrative of the great fluctuations which take place in the volume discharged by the river, the records for 1900 and 1902 might be quoted. In July, 1900, a sudden downpour of rain, aided by melting snows in the ranges forming the upper portion of the Lachlan gathering ground, caused the river to rise from 19 ft. to 46 ft. 8 in. in 26 hours at Cowra. The estimated discharge at this height was 1 800 000 cu. ft. per min. This volume was maintained for nearly two days, after which the river gradually subsided to its normal level. The total discharge for July, 1900, exceeded 19 000 000 000 cu. ft. The flood of 1894, although not at any time reaching the maximum recorded in July, 1900, was more sustained, as the river was in flood for four months of the year, and in that period not less than 66 600 000 000 cu. ft. passed the gauging station. By way of comparison, it may be mentioned that this was 60% more than the volume discharged by the Murray at Albury for the whole year 1902. During the drought year, 1902, the Lachlan was practically a chain of waterholes, and

Mr. Bellamy.

TABLE 36.

Name of river.	Situation of gauging station.	Maximum Annual Volume Passing Gauging Station.		Minimum Annual Volume Passing Gauging Station.		Maximum Recorded Discharge per Minute.		Minimum Recorded Discharge per Minute.		Catchment area, in square miles.	General remarks.

Darling........	Wilcannia...	717 000 000 000	1890	700 000 000	1890	....		....	......	......	From February, 1902, to January, 1903, the river ceased to flow on account of the drought. Gaugings from 1885.
Goulburn......	Murchison...	168 000 000 000	1887	27 753 000 000	1902	1 923 330	1887	4 000	Mch. 1902	9 000	During 1887 it is estimated that 35% of the total rainfall on the catchment area was discharged.
Ovens..........	Waugaratta.	82 948 000 000	1894	6 118 000 000	1902	658 000	1894	....	......	3 000	During 1902 it is estimated that only 5% of the total rainfall on the catchment area was discharged.
Mitta Mitta....	Tallaugatta .	87 987 000 000	1894	12 581 000 000	1902	922 100	1894	4 100	Jan. 1903	2 400	The run-off during 1902 was 10% of the total rainfall. Gaugings from 1886.
Kiewa	Kiewa	29 506 000 000	1894	7 021 000 000	1902	159 000	1889	200	Feb. 1900	700	During 1902, 23% of the rainfall on the catchment area passed the gauging station. Gaugings from 1885.

Mr. Bellamy. the discharge for the twelve months only reached 1 024 000 000 cu. ft., of which a very small proportion passed Condobolin.

The Brisbane River has a total water-shed of about 5 300 sq. miles, the areas of the principal contributing rivers and creeks, respectively, being as follows:

Stanley River	600 sq. miles
Brisbane River, above Cooyar Creek	166 " "
Mousildale and Avoca Creeks	190 " "
Cooyar Creek	410 " "
Emu Creek	380 " "
Maroughi and Anduramba Creeks	180 " "
Cressbrook Creek	230 " "
Lockyer Creek	1 160 " "
Bremer River	780 " "
Remainder (about)	1 370 " "

This area is bounded on all sides by mountain ranges varying in height from 1 000 to 4 000 ft. More than 2 500 sq. miles in the upper portions of the water-shed consist generally of impervious strata, and the lower portions, or remainder, of permeable strata. The Stanley River, rising in high lands near the Pacific Coast, is subject to intense rainfall which has a quick run-off; indeed, so much so, that it is considered the chief factor in studying flood flows in the main river. The total length of the Brisbane River is 210 miles; it is tidal for 53 miles, and navigable for vessels of more than 12 000 tons as far as Brisbane. The tidal range at the mouth of the river and at Brisbane is between 3 and 8 ft.

The valley of the Brisbane River is the scene of recurring floods, and the highest flood on record at Brisbane occurred on February 5th, 1893. The rainfall recorded for 8 days previous to that date at meteorological stations within the water-shed is as follows:

Cressbrook	20.97 in.
Crohamhurst	83.43 "
Esk	18.60 "
Fassifern	4.53 "
Ipswich	10.49 "
Laidley	10.81 "
Nanango	6.14 "
Woodford	38.87 " (gauge overflowed)
Brisbane	19.42 "

Unfortunately, these records are insufficient to give any reliable data as to the true average fall over the whole area; they are given because they are correct. The cross-section at the railway crossing by Indooroopilly carried the whole of the flood-water. The estimated surface

velocity of the current on February 5th was 10 miles per hour. The discharge in the 24-hour period of the flood, when at its maximum height, may be taken at 34 500 000 000 gal. Mr. Bellamy.

The Fitzroy River drains a catchment area of about 58 000 sq. miles, the greater portion of which is very flat; and of this area not less than 54 900 sq. miles are above Rockhampton, the capital of Central Queensland. The extreme length of the river, including all bends, measured from the source of the Dawson River Branch to its outlet in Keppel Bay, is 520 miles. The length within tidal influence, extending up to Alligator Creek, about 29 miles above Rockhampton, is only 62 miles. The greatest flood on record occurred in February, 1896, and the estimated maximum discharge of the river for a 24-hour period was 397 226 000 000 gal. The lowest flow ever recorded was gauged by the writer in May, 1902, when the small quantity of 46 000 000 gal. was discharged in 24 hours. The physical conditions of this river are entirely different from those previously referred to, chiefly on account of the water-shed being so very flat.*

In conclusion, the writer desires to state that he considers Mr. Fuller's paper to be the best and most instructive contribution yet published on the subject.

E. Kuichling, M. Am. Soc. C. E. (by letter).—The author is entitled to unstinted credit for having performed a vast amount of useful work in preparing his extensive compilation and ingenious analysis of flood records of American rivers. The subject is, moreover, a timely one, in view of the extraordinary floods which have occurred this year in Ohio and New York, last year in Wisconsin, and three years ago in Europe. From his studies of the data submitted, he reaches the conclusion that a general formula for computing the probable maximum flood discharge from catchment areas, must be provided with a factor, or coefficient, C, the magnitude of which depends on the peculiarities of each water-shed, and is adapted thereto by considering all previous flood flows therefrom; and, furthermore, that it must have another factor to express the ratio of the probable future maximum discharge to past smaller maxima, which factor is $(1 + 0.8 \log. T)$, wherein T denotes the number of years in the period between the recurrence of floods of approximately the same magnitude. The general formula proposed by the author for the greatest average rate of flow during 24 hours, in cubic feet per second, is $Q = C\,A^{0.8}\,(1 + 0.8 \log. T)$, in which A is the area of the catchment basin, in square miles. Mr. Kuichling.

The values of the variable factor, C, for the rivers of the several geographical districts of the United States, adopted by the U. S. Geological Survey, are given as computed by the author in Tables 12 to 26, inclusive. Two sets of such factors are given, one referring to the

* "On the Rainfall of Central Queensland and Floods in the Fitzroy River," by Herbert E. Bellamy, *Minutes of Proceedings*, Inst. C. E., Vol. CLXIII, p. 295.

Mr. Kuichling. average yearly flood discharge in a series of years, T, of observation, and the other to the largest observed discharge during such period. For the sake of clearness, they should be designated, C_1 and C_2, their values being expressed by $C_1 = \frac{Q\,(\text{Ave.})}{A^{0.8}}$ and $C_2 = \frac{Q'}{A^{0.8}\,(1 + 0.8 \log. T)}$, in Columns 8 and 7, respectively, of those tables. It seems to be the author's purpose to use the value, C_1, in his aforesaid general formula for Q, as he places $Q = Q\,(\text{Ave.})\,(1 + 0.8 \log. T)$, thus giving $Q = C_1 A^{0.8} (1 + 0.8 \log. T)$. The use of the formula may be illustrated by the following example relating to the Susquehanna River at Binghamton, N. Y., in Table 14, where $A = 2\,400$, $T = 10$, $Q\,(\text{Ave.}) = 39\,100$, $C_1 = 78$, and $C_2 = 70$, corresponding to $Q' = 63\,000$ cu. ft. per sec., which is the largest flow observed in 10 years. If it be desired to compute the probable maximum discharge, Q, that will occur in a period of $T = 100$ years, at the same place, the formula will become: $Q = Q\,(\text{Ave.})\,(1 + 0.8 \log. T) = 39\,100 \times 2.6 = 101\,660$ cu. ft. per sec.; and in a period of $T = 1\,000$ years, it will be $Q = 39\,100 \times 3.4 = 132\,940$. The coefficient, C_2, should not be used, as it relates only to the particular values, Q' and $T = 10$.

An examination of Tables 12 to 26, inclusive, shows wide differences in the values of C_1 for apparently similar drainage areas. Thus, in Table 14, we have $C_1 = 50$ for the Passaic River, with $A = 823$ and $T = 34$; while for the Raritan River, with $A = 800$ and $T = 6$, the value of C_1 is 93. Similarly, in the same table, we find for the East and West Branches of the Delaware River, at Hancock, N. Y., $C_1 = 140$ and 105, respectively, for $A = 920$ and 680, and $T = 9$ in both cases. Again, in Table 13, we find $C_1 = 58$ and 49 for the Hudson River with, respectively, $A = 2\,800$ and $4\,500$, and $T = 13$ and 40; while for the Mohawk River, with $A = 3\,440$ and $T = 12$, we have $C_1 = 75$; also, for the neighboring water-sheds of West and East Canada Creeks, with $A = 364$ and 256, and $T = 9$ and 12, we find $C_1 = 116$ and 71, respectively. For nearly equal areas in the basins of the Connecticut, Mohawk, and Delaware Rivers, namely, $A = 3\,305$, $3\,440$, and $3\,250$, with $T = 11$, 12, and 8, we have $C_1 = 49$, 75, and 97, respectively; and similarly with many other catchment areas. The values of C_1 also vary at different points in the same river basin, sometimes increasing with A, sometimes being nearly constant, and sometimes decreasing.

The factor, C_1, appears to depend primarily on the depth and extent of the precipitation causing a flood, the season of the year, and the total drainage area at the point of observation; and, secondarily, on the nature of the surface soil of the water-shed, whether absorptive or impermeable, the slopes of the surface and lines of drainage, the shape of the basin and its component areas, the extent and character of the vegetation thereon, the duration of the excessive

rainfall and melting of previously fallen snow, and the extent to which a portion of the run-off is impounded in natural and artificial reservoirs, including the temporary inundation of broad flats in the valley above the point of observation. The latter is an important feature, and, in considering the probable future maximum flow from such catchment areas, it will be expedient to assume that improvements will be made, whereby inundations will be reduced. The factor is also affected by the formation and bursting of ice jams in northern streams, and the formation of barriers of sunken logs, silt, and gravel, which may cause a large storage temporarily until scoured away by a strong freshet. It is thus evident that numerous features must be taken into account in estimating the probable maximum flow from a large area. Mr. Kuichling

In regard to the rainfall, it can be said that heavy precipitations covering great areas of country during a few days, occur at more or less regular intervals of years in all the States east of the Mississippi River and on the Pacific Coast. The points where the rainfall is observed, however, are generally so far apart that it is very difficult to estimate the actual volume and distribution of the water on a large territory. In mountainous regions, intense precipitations often occur in localities not provided with rain-gauges, and the fact that unusual downpours have taken place on areas of many square miles, is attested by the resulting freshets, the magnitude of which is not warranted by the scanty available records of rainfall at other places. It happens, therefore, that the rainfall on mountainous and hilly catchment basins is frequently underestimated, as shown by the case of the water-shed of West Canada Creek, N. Y., where in one year the aggregate run-off was much more than the estimated precipitation.

In view of the limited periods of flood observation on most American rivers, and the recurrence of heavy rainfalls at longer intervals of time, it becomes questionable whether the use of different values of C_1 for similar water-sheds in the same region is proper. The same combination of conditions that produced a great flood in one year in a particular basin, is likely to occur in another year in the neighboring basin, and hence it seems safer to use the largest observed value of C_1 for all the streams of a given region when it is known that the area, topography, and character of soil are substantially alike. The variation in the value of C_1 for larger values of A of similar water-sheds of a region, can probably also be deduced from the data, whereby C_1 will be expressed as a function of A; and, as a result, we will have a formula like $Q = B\ A^n\ (1 + 0.8 \text{ log. } T)$ for all similar catchment basins in a particular region. By this means regional peculiarities would be recognized by variations in the value of the coefficient, B, and perhaps also of the exponent, n. The ad-

Mr. Kuichling.

vantage of such a formula lies in its applicability to a wide range in the value of A.

A question also arises as to the value of T to be used when computing the future maximum flood discharge. The tables contain no reference to the rainfalls that produced the floods listed, nor to the dates of their occurrence, and hence it is impracticable to determine from the data submitted whether a probable maximum flood did not occur during the period of observation. It may also be that the largest observed flood was nearly equal to the future maximum, in which event the factor $(1 + 0.8 \log. T)$ would be correspondingly smaller than 2.5 or 3.0, when T is taken at from 75 to 320 years. Much depends, therefore, on the actual conditions which produced the observed floods, and on this subject no information is given in the paper. The floods of some of the rivers in Ohio, in 1913, were unprecedented in magnitude, and a statement that they might become twice as large in the future would surely have to be accompanied with the most convincing proofs in order to be accepted; and the same can also be said of all other large floods elsewhere.

In regard to the intervals between the occurrence of extraordinary floods, few data are available for American rivers. Table 12 shows that two great floods of nearly equal magnitude occurred in the Connecticut River, at Hartford, Conn., in a period of 104 years; two in the Merrimac River, at Lawrence, Mass., in 56 years; and two in the Androscoggin River, at Rumford Falls, Me., in 40 years. Table 13 shows that one great flood was observed in the Hudson River, at Mechanicsville, N. Y., in 40 years; Table 14, that two great floods were observed in the Passaic River, at Dundee Dam, N. J., in 34 years; Table 17, that two great floods occurred in the Genesee River, at Rochester, N. Y., in 128 years; Table 16, that two great floods of the Ohio River, at Wheeling, W. Va., occurred in 50 years; and Table 20, that one large flood of the Kansas River, at Lecompton, Kans., occurred in 60 years, all other periods of observation being less than 30 years. The average of the foregoing enumeration is one great flood at intervals of 37 years, or a total of 14 in 512 years.

For foreign rivers, a few data as to recurrences of great floods were recently published in official investigations of floods of the Seine, at Paris, and the Danube, at Vienna.* In the Seine at Paris, the observations extend over a period of 400 years, the highest flood having occurred on March 1st, 1658, and the next almost equally high one on January 28th, 1910; the third in order of magnitude, and but slightly lower than the second, was on December 26th, 1740, and between this date and January 7th, 1883, eight other floods of somewhat lower height are recorded. We thus have for the Seine a record of 11 great floods

* Abstracts thereof are given in *Engineering News*, 1910, I, p. 327, and *Zeitschrift* des Oesterr. Ingenieur- u. Architekten-Vereines, 1910, pp. 147 and 457, respectively.

Mr. Kuichling.

in 255 years, or on the average one unusual flood in 23 years. The discharge of the river at Paris, on January 28th, 1910, was estimated at 83 500 cu. ft. per sec. from a water-shed of about 16 860 sq. miles.

At Vienna the drainage area of the Danube is about 39 200 sq. miles, and from well-attested flood marks, the highest flood occurred in 1501. No reliable data for computing the discharge at that time are available, but, as nearly as can be determined from observations of the river channel during the past 50 years, the maximum flow was then about 503 200 cu. ft. per sec. Numerous smaller floods have occurred since, with discharges reaching 370 800 cu. ft. per sec. in September, 1899; but from a careful study of all existing data relating to the precipitation on the drainage area, the engineer who reported on the subject in 1910 concluded that a recurrence of the great flood of 1501 was highly probable, and might take place in any year of excessive rainfall.

Other records for European rivers might also be cited, to show that great floods have occurred in shorter intervals than 100 years; but it is believed by the writer that enough has been adduced to show that the proper value of T to be used in making estimates of future flood flows of American rivers, deserves further explanation by the author.

Generous reference has been made in the paper to the writer's extensive study of the subject, as published in the State Engineer's "Report on the Barge Canal of the State of New York", Albany, 1901. In this publication the drainage areas and maximum flood discharges, in cubic feet per second per square mile, of 232 American and 364 foreign river basins were submitted, together with 18 different formulas, reprinted in Table 29, that had been devised up to 1900 by various engineers for estimating the probable maximum flow of a stream. Although these data are very useful, they are too long for reproduction here, especially as many of them are contained in the author's tables, and therefore the writer will append only the additional data on large flood discharges that he has collected since the year 1900.

An examination of the figures soon shows wide differences in the rates of maximum discharge for water-sheds of the same magnitude in different parts of the world, and confirms the view of the author that it is necessary to take into account the topographical, geological, and meteorological characteristics of a drainage area before estimating the probable maximum run-off therefrom. This opinion has long been held by hydrologists, and hence most of the various formulas for flood discharge are adapted only to particular localities. Doubtless the most important factors are the intensity, duration, and distribution of the rainfall on the water-shed, but owing to lack of sufficient data on this subject in almost every country and State, it becomes extremely difficult to establish even an approximately correct relation

Mr. Kuichling.

between them. For rains of comparatively long duration, the character of the surface soil seems to be of minor importance, as the ground usually becomes saturated in a few hours and absorption diminishes in large degree; whereas, for short heavy downpours, the condition of the soil and the vegetation thereon is of great influence on the run-off, especially as the area covered by such precipitation is then relatively small. The largest rate of run-off that the writer has found recorded is 3 200 cu. ft. per sec. per sq. mile, on July 14th, 1897, from an area of only 0.25 sq. mile of irregular rocky surface on Beacon Mountain, near Fishkill, N. Y.

Reference may also be made to the following formula* of R. Iszkowski, Chief Engineer of the Austrian Ministry of Public Works. This is called an "induction formula for estimating the normal and flood discharges, based on the characteristics of the water-shed," and involves four direct factors, viz.: the area (M) of the water-shed; the mean yearly depth (R) of rainfall thereon; two variable coefficients, one (C_1) depending on the topography or general slope of the territory, and the other (C_2) on the character of the surface soil, according as it is strongly absorptive, slightly permeable, or impervious; and lastly, a special factor (m) which varies inversely with the area of the water-shed. In its original form, for the metrical system, this formula is $Q_{max.} = (0.022\ C_1 + mC_2)\ R\ M$, where $Q_{max.}$ is the probable maximum flood discharge, in cubic meters per second, (R) is the mean annual depth of rainfall, in meters, and (M) is the drainage area, in square kilometers. For this system of measures, the value of the coefficient (C_1) ranges from 0.20 for very flat, sandy, or swampy areas, to 0.65 for high mountainous areas; the value of (C_2) ranges from 0.035 for very permeable land covered with vegetation to 0.70 for impervious rocky or frozen land, without active vegetation, and covered with snow which will increase the run-off by melting; and the value of (m) ranges from 7.88 for $M = 10$ sq. km. to 0.65 for $M = 100\,000$ sq. km., as set forth in a table from which the writer has deduced the approximate relation: $m = \dfrac{0.59\ (11\,050 + M)}{818 + M}$. For average conditions, such as correspond to a hilly territory with slightly permeable soil and sparse vegetation, the values of the said coefficients are $C_1 = 0.385$ and $C_2 = 0.40$. By substituting these particular values in the formula and then reducing to the customary measures of discharge (q) in cubic feet per second per square mile, area (M) in square miles, and the mean annual depth of rainfall (R) in inches, we will have:

$$q_{max.} = \frac{0.568\ .\ R\,(4\,129.5 + M)}{315.8 + M} \qquad \text{.................} (1)$$

* Published in *Wochenschrift* des Oesterr. Ingenieur- u. Architekten-Vereines, Vol. 9, 1884, pp. 25, 33, and 146.

Mr. Kuichling.

in cubic feet per second per square mile, for the aforesaid average conditions. If we assume $R = 36$ in., this expression will give $q_{max.} = 260, 208, 80$, and 28 for $M = 10, 100, 1\,000$, and $10\,000$, respectively. For mountainous territory with rocky or frozen soil, we will have $C_1 = 0.50$ and $C_2 = 0.60$ in the original formula, whence by reduction:

$$q_{max.} = \frac{0.848 \,.\, R\,(4\,147.4 + M)}{315.8 + M} \dots\dots\dots\dots\dots (2)$$

in cubic feet per second per square mile. For the same values of (R) and (M) as before, this second equation gives $q_{max} = 390, 312, 119$, and 42, or 50% more than by Equation (1). Similar expressions might also be deduced for other values of (C_1) and (C_2), but they will be omitted here as it is doubtful whether the formula can be applied generally without modification. In the writer's opinion, the formula gives values of (q) that are too low for small drainage areas and too high for large ones. The method of development, however, is ingenious and worthy of closer investigation.

On page 616 of the paper a formula is given that was devised by the writer in 1900 for the probable maximum flood discharge from mountainous and hilly water-sheds of not more than 5 000 sq. miles in the Middle and New England States. Since that time many other data have become available, so that this formula should now be modified. Further studies of the subject have led the writer to propose another simple formula which applies to river basins in the Southern Atlantic States, and is based on the greatest observed discharges of the Potomac River at Point of Rocks, Md., the New River at Radford, Va., the Catawba River at Rock Hill, N. C., the Little Tennessee River at Judson, N. C., Cane Creek at Bakersville, N. C., and numerous other streams which exhibit somewhat smaller rates of discharge than the preceding. This new formula is

$$q_{max.} = \frac{41.6\,(620 + M)}{24 + M} \dots\dots\dots\dots\dots\dots (3)$$

in cubic feet per second per square mile, and it may be regarded as applicable to mountainous and hilly water-sheds having areas of not more than 10 000 sq. miles, in the portion of the country indicated. In comparison with Iszkowski's data, as represented by the foregoing Equation (2), this formula gives $q_{max.} = 771, 242, 66$, and 44, respectively for $M = 10, 100, 1\,000$, and $10\,000$ sq. miles. A great difficulty is found in estimating the discharge from cloudbursts on basins of less than 50 sq. miles, as both the duration of the heavy rainfall and the area covered by it are indefinite; hence it is likely that a modification of this new formula will also be required.

Mr. Kuichling.

TABLE 37.—UNUSUAL FLOOD DISCHARGES, SUPPLEMENTARY TO THE DATA COMPILED BY THE WRITER, AND PUBLISHED IN THE REPORT ON THE PROPOSED BARGE CANAL FOR THE STATE OF NEW YORK, ALBANY, 1901, pp. 845-865. ARRANGED ACCORDING TO MAGNITUDE OF DRAINAGE AREA.

Stream and locality.	Drainage area, in square miles.	Maximum discharge, in cubic feet per second per square mile.	Date of flood.	Number of years observed.	Authority.*

Robert E. Horton, M. Am. Soc. C. E. (by letter).—On page 610, Mr. Fuller states that: Mr. Horton.

"As far as the writer knows, the first suggestion of the use of the element of time in a formula for flood flows was made by Allen Hazen, M. Am. Soc. C. E., in a memorandum written by him in 1910."

It is not disputed that the idea of the use of the element of time in the discussion of flood flows may have occurred to Mr. Hazen independently, but in deference to the late George W. Rafter, M. Am. Soc. C. E., the writer feels obliged to deny that the idea originated with Mr. Hazen. This idea, as to its application to floods and also to other hydrological data, was suggested to the writer at least as early as 1896, or 14 years before it was suggested to Mr. Fuller by Mr. Hazen.

Mr. Horton. It was Mr. Rafter's desire that the writer should prepare the data for a paper on the application of the Theory of Probability to Flood Flows and other hydrological data, and the matter was discussed frequently and fully during the years 1896 to 1904. It appeared at that time, however, that stream flow data were so meager as to make it desirable to defer the completion of the studies. The writer continued the studies, as occasion arose, using the ordinary law of probability where the data were too meager to permit of plotting a satisfactory special probability curve on logarithmic paper.

In 1896 the writer had prepared, at Mr. Rafter's request (by letter dated October 25th, 1896), an analysis of the rainfall and run-off of the Upper Hudson Drainage Basin, in which the probable average interval of recurrence of run-off less than the observed minimum was determined by the Theory of Probability. This and similar phenomena were analyzed by the ordinary method of probability, through the use of the so-called Gaussian Law of Error.*

It was recognized at that time that the Gaussian Law did not represent accurately the law of frequency of recurrence of many hydrological events, and an effort was made first to find a better general law† and to deduce individual laws. For the latter, the method of plotting flood records on logarithmic paper was tried, and proved so promising that, between 1900 and 1908, many logarithmic probability curves were plotted by the writer and corresponding formulas deduced, involving time as an element; and the methods and results have been applied extensively in professional practice by the writer for a period of several years.

He also applied the method of analysis of flood data by logarithmic special probability curves to the determination of maximum navigable stages, capacity of waste-weirs, etc., in connection with his work as Resident Engineer in Charge of the Bureau of Hydraulics of the New York State Barge Canal.

These results, after discussion with other engineers of the Department and with the Advisory Board of Consulting Engineers, were used as a basis in the design of work costing some millions of dollars. In this work the writer adopted 100 years in most cases as the average interval of recurrence of a flood of the magnitude to be made the basis of design. For the determination of relative frequencies of floods of different magnitudes on small torrential drainage basins in the Upper Mohawk River area, for which flood records were mostly wanting, the writer used as a basis of comparison in 1906 logarithmic flood dis-

* Report of State Engineer and Surveyor of New York, 1896, p. 841 *et seq.*

† In a letter dated August 11th, 1897, Mansfield Merriman, M. Am. Soc. C. E., suggested to the writer the use of a function of the form $y = (x + a)^2 (x - b)^2$ for this purpose.

charge formulas which he had previously deduced for the Neshaminy, Tohickon and Perkiomen, as follows: Mr. Horton.

$$Q = 30\ T^{0.25} \text{ for the Neshaminy,}$$
$$Q = 30\ T^{0.27} \text{ " " Perkiomen,}$$
$$Q = 40\ T^{0.25} \text{ " " Tohickon,}$$

in which Q = flood discharge equalled or exceeded in an average interval of T years, in cubic feet per second per square mile.

These formulas were based on 20 years' records of the streams, covering the period, 1885-94. They give the results shown in Table 38.

The writer also deduced the following general formula, applicable to these and similar drainage basins:

$$Q = 4\,021.5 \frac{T^{\frac{1}{4}}}{A},\ T = \sqrt[4]{\frac{Q\ A}{4\,021.5}}$$

or, as a logarithmic formula,

$$\log. Q = 3.6043881 + \frac{1}{4} \log. T - \log. A,$$

in which A = drainage area, in square miles; other notations as in Table 38.

TABLE 38.

Stream.	Drainage area, in square miles.	Interval, T, in Years.				
		1	10	25	50	100
		Cubic feet per second per square mile.				
Perkiomen	152	29.7	49.6	60.5	70.5	82
Neshaminy	139.3	29.4	55.0	71.0	85.5	104
Tohickon	102.2	40.5	71.0	89.0	105.0	125

In view of the foregoing considerations, the writer fails to discover wherein there is any proper basis for a claim of originality for this method, as far as the use of time as an element in flood formulas is concerned, as set forth in the paper. The writer does not claim any great breadth of applicability for the general formula just given, but believes that factors other than area modify the flood discharge of streams so profoundly that it is better, wherever possible, to derive individual formulas or flood-frequency diagrams for each stream. Following this idea, he deduced flood-frequency diagrams in 1906-08, for use in connection with the New York Barge Canal work, for the Mohawk, Hudson, Oswego, Seneca, and other streams. He has deduced and used similar special probability curves and logarithmic formulas to determine the law of frequency of recurrence of various other hydro-

Mr. Horton.

logical events, such as minimum seasonal rainfall, duration of periods without rain, relative probability of floods in different months of the year, minimum run-off of streams, storage volume required to maintain a constant supply from a stream, rain intensity of various durations, etc.

Attention may properly be called to another study, utilizing the same principles, which seems to antedate Mr. Hazen's suggestion of 1910, namely, the rain intensity diagram and formulas of J. de Bruyn-Kops, M. Am. Soc. C. E., for Savannah, Ga.*

With reference to the Neshaminy, Perkiomen, and Tohickon flood formulas derived by the writer in 1904, as given in Table 88, it should be noted that these were derived in such a manner as to include all floods exceeding a given magnitude, and not merely the greatest single day's flood of each year. The writer's usual method of deriving a formula for the frequency of annual floods which will equal or exceed a given limit is similar to that described in Table 5, Part *c*, except that in his analysis Mr. Fuller discards all floods less than the mean, and works from ratios. The writer utilizes all annual floods, both greater than and less than the mean, although it is sometimes necessary to use a different flood formula for floods of low intensity. He also prefers to work directly from the original data rather than by reducing the data to the form of ratios.

Mr. Fuller says of his general formula, as given on page 567.

"$Q = CA^{0.8}$ $(1 + 0.8 \log. T)$, in which Q is the largest 24-hour average rate of flow to be expected in a period of T years."

Tracing out the derivation of this formula (given on pages 576-580), it appears that Q is there defined as the "average maximum flood," and the meaning of this term appears to be quite different from that first given.

Assuming that Mr. Fuller's formula represents the average magnitude of floods having an average interval of recurrence greater than T, it may also be said that it represents the magnitude of a flood which will be equalled or exceeded at some average interval greater than T, but that this interval is unknown and cannot be determined from his formula. This illustrates the indefiniteness of his formulas when applied to the problem of flood determination, in the form in which, from the writer's experience, this problem usually occurs.

Again, in the case of Tohickon Creek, Mr. Fuller apparently does not mean by his formula for the average maximum flood of that stream, $Q = Q$ (Ave.) $(1 + 0.76 \log. T)$, that we may expect a flood at least as great as, or in other words, equal to or greater than 6 300 cu. ft. per sec. once in 5 years, for his own analysis of the same data (Table 5, Part *c*) shows that we may expect a flood to equal or exceed

* *Transactions*, Am. Soc. C. E., Vol. LX, p. 248.

6 300 cu. ft. per sec. on an average only once in about 10 years, or one-half as often. **Mr. Horton.**

On reading the paper carefully, the writer is of the opinion that the author has failed to set forth clearly the meaning of his own deductions. The writer's understanding of the matter is as follows, referring to Table 5, Part *a*, for Tohickon Creek.

The average magnitude of maximum floods having average intervals of recurrence between 5 and 25 years is 1.53 times the mean flood, or 6 300 cu. ft. per sec.

The average magnitude of floods having intervals of recurrence between 2.50 and 25 years is 1.29 times the mean flood, or 5 310 cu. ft. per sec., and so on.

The results of the author's general formula bear the same interpretation, except that it is probably approximately true, from the method of analysis used, that Q, in the formula, represents approximately the average volume of all floods having an average interval of recurrence greater than T, it being here assumed that the formula is correct for the particular stream in question.

What Mr. Fuller has really deduced is not the average magnitude of the floods having, for example, 25 years or 12.5 years average interval of occurrence. Statistically speaking, there can be only one magnitude of the maximum flood having, for example, 25 or 12.5 years average interval of recurrence. The appellation "average maximum flood" of a given interval of recurrence seems to be misleading and inaccurate. If we had a long enough record, and were to divide it up arbitrarily into 25-year periods, and were to take the average of the maximum floods of each period, we would get a quantity having some semblance to a maximum average flood of 25 years interval, but the writer fails to see any practical value in such a result. Furthermore, the result would obviously be very likely to be affected by the mode of dividing up the record, which condemns the method.

Take, for example, the 5-year Tohickon flood of 6 290 cu. ft. per sec. The author does not mean that we may expect a flood of just this magnitude on an average of once in 5 years. As a matter of fact, the probable average interval of recurrence of a flood of just this magnitude is very much greater than once in 5 years.

The writer cannot see that results in the form of the "average maximum flood" are of much practical use, but, if any one wants them, they are derived more easily and directly by the method shown in Table 5, Part *c*, than by the method used by the author.

In addition, it would seem that the method of Table 5, Part *c*, when properly applied, has several other decided advantages.

1.—It is simpler of application, requiring three columns instead of five.

Mr. Horton.

2.—It gives directly the average interval of recurrence of a flood equal to or greater than a given magnitude. This is a factor of great importance, and has direct application in designing spillways, determining high navigable stages of waterways, etc.

3.—It enables the average interval of recurrence of a flood lying between any two given magnitudes to be readily determined.

For example, from Table 5, Part *c*, the average interval of Tohickon floods at least 1.21 times the mean, or 4 968 cu. ft. per sec., is five years. Their probability is, therefore, $\frac{1}{5} = \frac{5}{25}$.

The average interval of floods of at least 1.45 times the mean, or 5 958 cu. ft. per sec., is 8.33 years. Their probability is, therefore, $\frac{1}{8.33} = \frac{3}{25}$. The probability of a flood between 4 968 and 5 958 cu. ft. per sec. is, therefore, $\frac{5}{25} - \frac{3}{25} = \frac{2}{25} = 0.080$, or the probable average interval of recurrence of a flood between 4 968 and 5 958 cu. ft. per sec., or of a flood having an average of about 5 460 cu. ft. per sec., is 12.33 years. Now, if Table 5, Part *a*, and the formulas deduced by the method there given, mean what the author says they do, would we not expect floods of this average magnitude to occur at intervals of about 3.57 years, instead of 12.33 years, as actual experience shows to be the case? This illustrates what seems to be a fatal error in the author's method of analysis.

It would appear that the relation between flood magnitude and frequency, when expressed in terms of either "average maximum flood" or "median flood," is not only very indefinite and difficult of comprehension, but is apt to be very misleading, if it is not indeed practically meaningless. It does not directly convey the information which the engineer usually most desires, for example: If a spillway has a capacity of 1 000 cu. ft. per sec., how often on an average will its capacity be exceeded?

Further, in Tables 4 and 5 for Tohickon Creek, the author has arbitrarily excluded from consideration all floods which did not exceed the average yearly one of 4 117 cu. ft. per sec. He has excluded thirteen floods and used eleven. Instead of following the rule "of making the best possible use of all the available information", he has made no direct use of considerably more than half of it. What the author was seeking was, it may be assumed, to find the law defining the relation between the magnitude of floods and their relative frequency of recurrence. If one were seeking to determine the law of velocity of falling bodies, and had 25 observations of the time required for different weights, varying from 10 to 60 lb., to fall through given heights, it would hardly be considered good scientific method to discard *a priori* all observations on weights of less than 35 lb.

Mr. Horton.

Mr. Fuller's method of working with ratios (Table 5), instead of actual flood volumes, seems to be confusing and cumbersome. The data which the engineer has to start with are actual flood volumes; what he desires to determine, as a rule, as in designing a spillway, is a flood volume which will not be equalled or exceeded on an average oftener than once in a given interval, say, 100 years.

If we had two drainage basins, A and B, which were similar figures, with similar drainage systems, or "stream nets" as the German hydrologist calls them, and identical in geology, soil, topography, slope. culture, and climate, but if A were larger than B, and if Q_A and Q_B were the true maximum 24-hour floods to be expected on these streams in an average interval of T years, then the difference between Q_A and Q_B would be the difference in flood-yielding capacity due to area alone.

In practice, however, it often happens that one area much larger than another does not yield a materially larger flood. If the data of such heterogeneous basins are plotted together in terms of area as abscissas, it appears to the writer that the results will be so discordant as to render the conclusions drawn therefrom of doubtful value.

Here we come squarely against the question of the physical, and not merely the statistical, aspects of the question. The latter only are covered by Mr. Fuller's discussion.

In the climate of the North Atlantic States local thunder storms nearly always produce maximum floods on very small areas, though only broad general cyclonic storms produce floods on the larger and medium large rivers, like the Hudson, the Susquehanna, and the Delaware. Now, thunder storms produce rains of great intensity but short duration. Broad cyclonic storms produce rains of low intensity but long duration, so that the relative flood intensity for different areas is not wholly determined by the relative times required for the water to reach the stream, or by the physiographic or cultural conditions, but partly by purely meteorological conditions.

The paper contains a valuable collection of flood data. It would have been easy to include the dates of the maximum floods, and these would be of use to engineers in comparing simultaneous flood intensities at different places. The writer cannot help feeling a sense of regret that so much labor has been expended in analysis of flood data along lines that do not seem to be either the most scientific or the most useful to engineers.

The ambition to place the results of one's investigations in the hands of the Profession at the earliest date is laudable, if indulged in with moderation. The writer's only excuse for withholding from publication the results of his own studies along similar lines for so long a time is that he thought it better to try the method out in prac-

Mr. Horton.

tice first, rather than run the chance of punishing the Profession by the publication of that which might later prove to be premature.

The writer happens to have collected all the data contained in Table 13. Many of the floods there listed have subsequently been exceeded.*

Mr. Pillsbury.

G. B. Pillsbury, Assoc. M. Am. Soc. C. E. (by letter).—Accepting the premise that the magnitude of a flood is due to the combination of an unlimited number of accidental causes, the probability of the occurrence of a flood exceeding a given magnitude should follow the well-established laws of probability as deduced in the theory of errors of observations. Under these laws the probability of an annual flood less than a given value, Q', is given by the formula:

$$P = \frac{h}{\sqrt{\pi}} \int_0^k e^{-h^2 x^2} dx \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (1)$$

and of an annual flood greater than Q'

$$P = \frac{h}{\sqrt{\pi}} \int_k^\infty e^{-h^2 x^2} dx = \frac{1}{\sqrt{\pi}} \int_t^\infty e^{-t^2} dt \ldots\ldots (2)$$

where $k = Q' - Q$ (Ave.) and $t = h\,k$.

The value of h is given by the formula:

$$h = \sqrt{\frac{n-1}{2 \Sigma v^2}}$$

where n is the number of floods observed and Σv^2 is the sum of the squares of the residuals of the observed values with relation to the average yearly flood.

The reciprocal of P, Equation 2, will then represent the period of years in which, in the long run, an annual flood equalling or exceeding Q' may be expected.

The usual probability tables give the value of the function, $\frac{2}{\sqrt{\pi}} \int_0^t e^{-t^2} dt$, from which the function, $\frac{1}{\sqrt{\pi}} \int_t^\infty e^{-t^2} dt$, in Equation 2 can be computed from the relation,

$$\frac{1}{\sqrt{\pi}} \int_t^\infty e^{-t^2} dt = \frac{1}{2} \left(1 - \frac{2}{\sqrt{\pi}} \int_0^t e^{-t^2} dt\right).$$

The author, however, has taken the average value of the annual floods equalling or exceeding the given value as his measure of the

* Reports on Hydrography (by the writer), State Engineer's Reports, 1900, 1912; also paper on "Effects of Recent Flood on New York Streams," *Engineering Record*, April 12th, 1913.

Mr. Pillsbury.

expected flood, and not the flood of magnitude which would be derived from Equation 2.

The mathematical expression for this average or mean of floods exceeding Q' is

$$Q = Q\,(\text{Ave.}) + \frac{\dfrac{h}{\sqrt{\pi}} \displaystyle\int_k^{\infty} x\, e^{-h^2 x^2}\, dx}{\dfrac{h}{\sqrt{\pi}} \displaystyle\int_k^{\infty} e^{-h^2 x^2}\, dx}$$

$$= Q\,(\text{Ave.}) + \frac{1}{h}\;\frac{\dfrac{1}{2\sqrt{\pi}}\, e^{-t^2}}{\dfrac{1}{\sqrt{\pi}} \displaystyle\int_t^{\infty} e^{-t^2}\, dt} \quad \ldots\ldots(3)$$

$$= Q\,(\text{Ave.}) + \frac{1}{h}\, M \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots(4)$$

It is obvious that this mean value is somewhat greater than its inferior limit.

Table 39 shows the relation between the time, T, considered (or the reciprocal of P in Equation 2), and the value of M (Equation 4).

Taking the floods of Tohickon Creek, as given by the author in Table 4, the computation of the mathematical values of average maximum flood, under the theory of probabilities, is shown in Table 40.

The probable average maximum floods, according to the theory of probabilities, and the observed averages as determined by the author, are plotted on Fig. 14.

Mr. Pillsbury.

Table 41 and Fig. 15 show the floods of the Connecticut River at Hartford for 70 years, beginning 1843. The observed average maximum floods shown on the figure are computed in Table 42.

The floods of the Allegheny River at Kittanning for a 41-year period are tabulated in Mr. Knowles' discussion, Table 35. The value of h, as derived from these data is 2.03. The curve of probable average maxima, the author's curve, and the observed values, are plotted in Fig. 16.

A very cursory examination of the figures shows that, for individual rivers, the observed average maxima differ widely, both from the author's formula and from their theoretical values under the theory of probability. This, indeed, is not extraordinary. The highest of the plotted observed figures is but a single flood, and not an average. The first few of the succeeding observed averages are based on very limited data, and may be expected to differ from their theoretical values in the long run. In the case of Tohickon Creek, the extraordinarily large value of the maximum observed flood has a very great bearing in the large values of the next lower averages.

The application of the law of probability to the maximum average floods, as given by the writer, is intended merely as a side light on the

discussion, it being excessively cumbersome for useful computation. It appears to the writer, however, that the application of the theory to streams with long records shows that the formula of the author will often give far too high values to the flood to be expected in such a long period as 1 000 years—which is another term for saying ever expected. Thus, in the Connecticut River at Hartford, the author's formula **Mr. Pillsbury.**

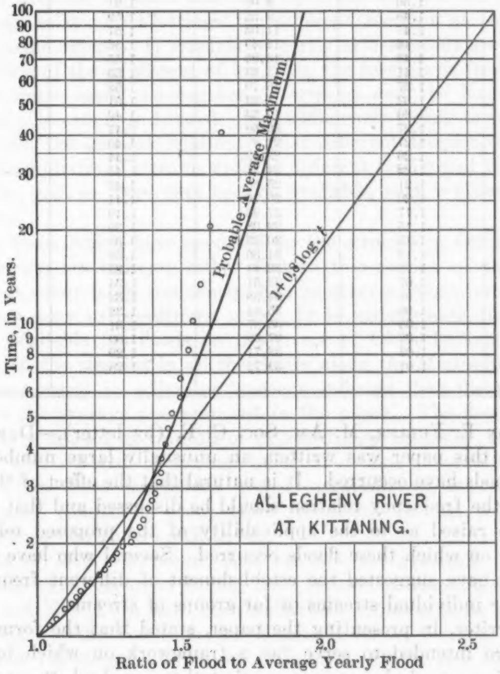

FIG. 16.

shows that a flood of 3.4 times the average, or of about 380 000 cu. ft. per sec., is to be expected in a period of 1 000 years. Dropping the somewhat cumbersome average maxima, the theory of probabilities indicates that the chance of a flood twice the average, or 225 000 cu. ft. per sec., is but one in 1 000. Would an engineer be justified in constructing works to care for more than, say, 250 000 cu. ft. per sec.?

Mr. Pillsbury.

Mr. Fuller.

WESTON E. FULLER, M. AM. SOC. C. E. (by letter).—During 1913, and since this paper was written, an unusually large number of disastrous floods have occurred. It is natural that the effect of these great floods on the frequency relation should be discussed and that questions should be raised as to the applicability of the proposed relations to the rivers on which these floods occurred. Several who have discussed the paper have suggested the establishment of different frequency relations for individual streams or for groups of streams.

The writer, in presenting the paper, stated that the formulas proposed were intended to serve "as a framework on which to arrange the data in an orderly manner, so that they can be better understood and more readily used." With this object in view, formulas were derived which expressed the average frequency relation for the floods which have occurred on many rivers widely distributed over the country. Tables were presented giving values of the coefficient, C, as obtained from the average yearly flood for such rivers as had been observed a sufficient number of years to give an approximate idea of the size of this average. In these tables were also included other values of C, obtained by reducing the larger floods by the use of the proposed formula. These latter values of C indicate how the actual

floods which have occurred on the rivers have agreed with the proposed formula. The close agreement, for most of the rivers, of these two sets of coefficients indicates that the relation is a general one. During the course of the study on which the paper was based, plottings were made for many individual streams and for groups of streams in different sections of the country. The effect of the few larger floods on the plottings for individual streams was so great that the writer concluded that the relation indicated by them was less accurate than the average relation. Plottings for different sections of the country varied to some extent. If streams in partly arid sections are excluded, the variation of the coefficient of log. T in the formula is from 0.7 to 1. In the extreme cases the number of streams and the length of the records were too short to furnish proof sufficiently strong to justify any change from the general relation. That different frequency relations do exist for individual streams and for different sections of the country is probable, and, as more data become available, such relations may be established. Mr. Fuller.

Great floods which have occurred on the streams in Ohio since the paper was written indicate either that in this section of the country great floods occur more frequently than in other sections, or that these floods were very extraordinary ones. It is unfortunate that so few data are available for floods on the rivers of Ohio, Indiana, Illinois, and, in fact, the streams in all the States along the Mississippi Valley. Floods on streams in adjoining sections indicate that the relation is similar to the average one proposed in the paper. The floods of 1913 in Ohio were caused by rainfall of extraordinary intensity, considering the large area covered, occurring under conditions favorable for great floods. That these conditions were extraordinary is certain, but whether such conditions occur more frequently in this section than elsewhere only the future will show.

Floods of 1913.—Although data are not yet available for all the great floods which occurred during 1913, records of those on some rivers in Ohio and New York have been published. Among those of particular interest are the floods on the Miami River at Dayton, Ohio, the Scioto and Olentangy Rivers at Columbus, Ohio, and the Hudson River at Mechanicsville, N. Y. The data for these rivers, revised to include the records of 1913, are given in Table 43.

The value given for the ratio between the flood of 1913 and the average flood for the streams at Columbus corresponds to a value of T equal to about 1 400. As there are more than 1 400 records of floods on different rivers for which the ratios to the average flood are now available, the occasional occurrence of such a flood is not surprising.

For the Miami River at Dayton, Mr. Morgan expresses the opinion that the coefficient, C, in the writer's formula should not exceed 50. If this were the proper value for C, the 1913 flood on the Miami

Mr. Fuller.

* Represents rate at maximum stage.

The data for the floods at Columbus are from the "Report on Flood Protection for the City of Columbus" by John W. Alvord and C. B. Burdick, Members, Am. Soc. C. E.

The data for the maximum flood at Dayton are from the discussion by Arthur E. Morgan, M. Am. Soc. C. E.

The data for the maximum flood on the Hudson are from *Engineering Record*, April 12th, 1913, "Effect of Recent Floods on New York Streams" by R. E. Horton, M. Am. Soc. C. E.

River would be relatively very greatly in excess of any flood which we have known on other rivers. The data on which to base the value of C for the Miami are not very satisfactory. In the papers of the U. S. Geological Survey there are 4 years, 1906 to 1909, inclusive, for which floods at Dayton are recorded. An average of these four floods would indicate a value of C of about 86. The best indication of the average flood at Dayton is that deduced from the gauge heights of the U. S. Weather Bureau, which are available for 21 years. As the rating curve for large floods is indefinite, it seems best to obtain the average flood by means of the median gauge height during this period. This has been 11.9, corresponding to a flood of about 39 000 cu. ft. per sec., according to the rating by the U. S. Geological Survey in 1906. During the last 10 years the median gauge height has been 13.25, which corresponds to a flood of about 45 000 cu. ft. per sec. From other rivers it has been found that the median flood is usually less than the average by about 10 per cent. On this basis the average yearly flood on the Miami at Dayton, on the 24-hour basis, under present conditions, is probably at least 45 000, and the value of C is at least 90. The corresponding maximum rate of flow would be 50 000 cu. ft. per sec., or more.

During the past 20 years many changes have been made in the channel of the Miami, such as encroachment on the river channel in cities, and the construction of bridges with long approaches of solid embankment, which greatly reduce the waterway. It seems probable that the coefficient of C for the Miami River at the present time is different from what it was a number of years ago. Mr. Morgan thinks that the Miami should have a comparatively low coefficient of flow on account of the comparatively small average slope of the water-shed. Steep slopes on the upper branches with smaller slopes on the main

Mr. Fuller.

river and lower branches are conditions which may produce larger floods than uniform steep slopes. A comparison of the coefficients for different rivers of the same general character fails to indicate any great effect from the average slope of a river. The writer suggests that the relation between the slopes on different parts of the river and on its branches is of greater importance in determining the flood-producing capacity than the average slope.

The maximum flood on the Miami in 1913 may have been very different in magnitude from the flood which would have occurred if the channel had been unobstructed. The large number of embankments thrown across the valley, with inadequate waterways, provided temporary storage which tended to retard the earlier run-off until the branch streams poured in their maximum flood flows. The subsequent failure of these embankments releasing the stored waters, probably increased the flood materially.

Taking these matters into consideration, together with the great uncertainty of gauging such a flood, it seems probable that the recorded flood flow may have been considerably in excess of the flood which would have come under natural conditions. On the whole, the writer believes that the Miami flood of 1913 was not greater than five times the average yearly flood under present conditions, and that it may have been much less. At all events, the flood was a very exceptional one, and must be given careful consideration in determining the probable floods on our rivers, particularly those in the central part of the country.

The flood on the Hudson River in 1913 is an interesting one, from the standpoint of what may happen on other rivers. The maximum flood on the Hudson, for which records for many years are available, was, previous to this year, much less than what would normally be expected on the basis of its average flood. The flood of 1913, however, not only reached the normal maximum flood for the period of record, but exceeded it by a considerable quantity. There are many other rivers on which the maximum recorded flood is much less than the flood indicated by the average relation. That much greater floods will occur on some of these rivers within a comparatively short period seems assured. As an instance, the greatest flood on record on the Ohio at Wheeling and at Pittsburgh is equivalent to a flood which may normally be expected in a period of not more than 15 years. If a flood of the relative size of that on the Hudson occurs on the Ohio, it will mean a flood of more than 600 000 cu. ft. per sec. at Pittsburgh, or a flood from 4 to 5 ft. higher than the highest now on record.

Reliability of Frequency Relation as Established from Records on One Stream.—Messrs. Knowles, Horton, and Pillsbury give frequency relations for individual streams, which differ from the average relation

Mr. Fuller.

proposed by the writer. To show how unreliable such relations may be, Figs. 17 and 18 are presented, which show how greatly one or two of the larger floods affect the relation, even when derived from the longest records available for any stream.

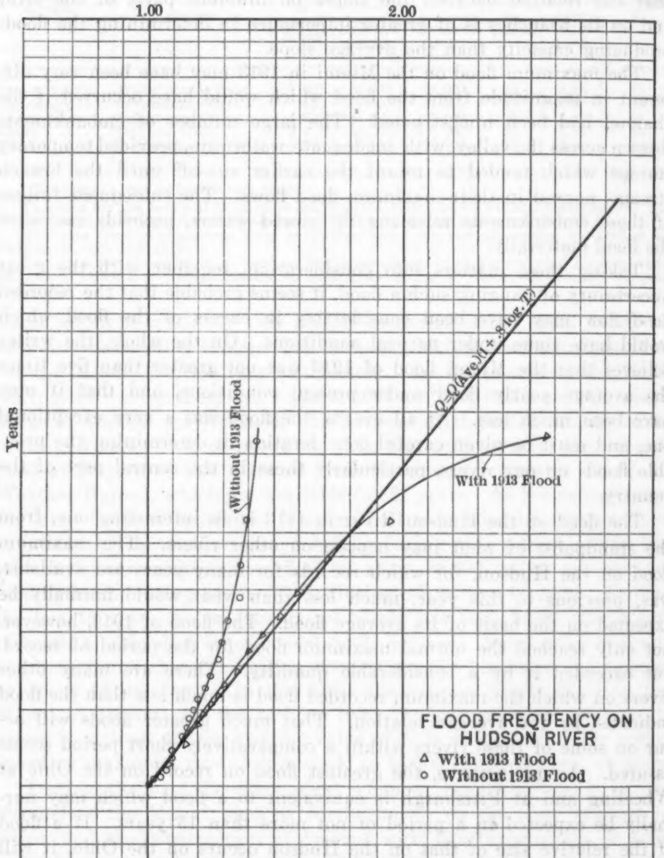

FIG. 17.

On Fig. 17 two curves illustrate the effect of a single great flood. The flood of 1913 on the Hudson is the greatest of which we have record. The effect of this flood is sufficient to change the data so that

the indications are just the reverse of what they were before the flood occurred. In other words, prior to 1913, the Hudson River records indicated that great floods occurred less frequently than on the average river. By including this flood in the data, the indications are that such floods occur with a greater frequency. Mr. Fuller.

Mr. Pillsbury contributes data for floods on the Connecticut River for 70 years, and Fig. 15 shows a frequency relation based on these data. Fig. 18 shows what the effect would be if two of the floods (which were actually about 1.5 times the average) had been somewhat greater. With this slight change the curves would be practically identical with the curves for eastern rivers, as shown on Fig. 1. In other words, the data for the Connecticut indicate a difference in frequency relation from the average of all eastern rivers only in that two floods are smaller than the normal. If any two of the seven or eight largest floods had happened to be greater by from 30 to 40%, the relation would have agreed with the general one. That such floods will occur on the Connecticut, and that, in another 70-year period, the data may indicate a relation equal to or exceeding the normal one, is probable. There are no continuous records for any streams in America of a length greater than that on the Connecticut, and the writer submits that curves, based on single records like those given in the discussions, do not justify any change of the relation from the average, unless other evidence is produced.

Comparison of Proposed Formula with Others.—Mr. Kuichling suggests a new formula, for use in the South Atlantic States, similar in form to his other well-known formulas. This and other formulas derived in a similar way give relatively higher values for small streams than the writer's formula. There is an essential difference in the meaning of these formulas which should be understood. The writer's formula gives the flood which will probably occur on the particular stream in question in a given interval of time. Mr. Kuichling's and other formulas, derived by plotting the maximum floods which have occurred on streams of different sizes, give the greatest flood which has occurred on any of the large number of streams in the varied intervals covered by the several records.

As there are many more small streams than large ones, it is obvious that there are more chances of obtaining an extraordinary flood on some one of the many small streams than there are of obtaining a similar flood on one of the few large ones.

As an illustration, take Mr. Kuichling's formula for the rivers of the South Atlantic States, which he states is

"based on the greatest observed discharges of the Potomac River at Point of Rocks, Md., the New River at Radford, Va., the Catawba River at Rock Hill, N. C., the Little Tennessee River at Judson, N. C., Cane Creek at Bakersville, N. C., and numerous other streams which

Mr. Fuller. exhibit somewhat smaller rates of discharge than the preceding. This new formula is

$$q_{max.} = \frac{41.6\,(620 + M)}{24 + M} \qquad (3)$$

in cubic feet per second per square mile, and it may be regarded as applicable to mountainous and hilly water-sheds having areas of not more than 10 000 sq. miles, in the portion of the country indicated."

There are probably fully 1 000 streams similar in size to that of Cane Creek for each one of the size of the Potomac. It is then to be expected that there will be many times as many chances of obtaining a single great flood on some one stream like Cane Creek as there will be of obtaining a flood relatively as great on a stream like the Potomac.

The formulas thus derived have an unbalanced element which must be taken into account. Mr. Kuichling has allowed for this to some extent, as his formula gives values much less than the recorded flood on Cane Creek, but the writer believes that the value given by the formula is still relatively too high.

The recorded sizes of floods, on streams like Cane Creek, Devil's Creek, and others which are greatly in excess of any well-verified flood discharges, are of doubtful value. A study of the methods used in gauging such floods shows that the measurements are obtained from slopes and sections taken after the flood. Little is known of the conditions which existed during the flood, and the apparent slope is often in error. High-water marks may have been caused by the backing up of the water by obstructions which afterward passed on under the flood pressures. The failure of structures may have caused great discharges for a short interval, which would not have occurred if the obstructions had not existed. The effect on the rate of flow of a stream due to the carrying of great quantities of débris which catch on fences, trees, and other obstacles causing eddies and reducing the channel area, is not known. If one may judge from experience with obstructions in pipes, this effect must be large. The effect of washing away the banks, the failure of bridges and dams, and of other matters which occur during such disastrous floods, is but little known. Flood discharges obtained by such methods are often not even approximately correct, and too much dependence should not be placed on them.

It may be well to state here that, in comparing the writer's formulas with others, the formula, $Q\ (\text{max.}) = C\ A^{0.8}\ (1 + 0.8 \log. T) \left(1 + \frac{2}{A^{0.3}}\right)$, should be used, as in most cases at least the maximum rate of flow is given by the other formulas.

Selecting a Value for C.—The selection of the proper value of C is important in the use of the proposed formula. Before its selection, a study of the flood data on the stream in question and on other

Mr. Fuller.

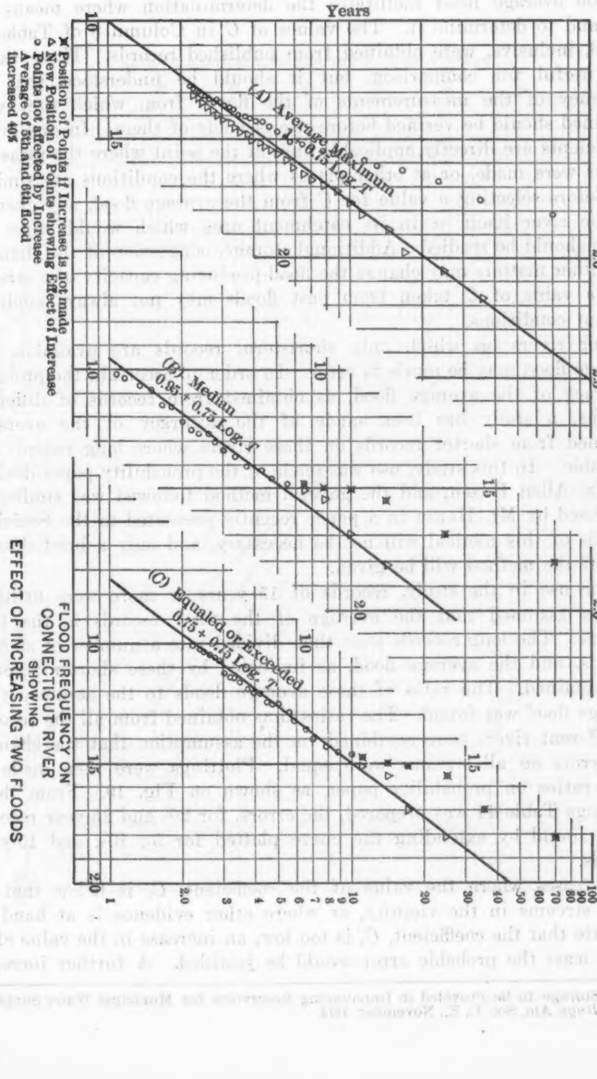

FIG. 18.

FLOOD FREQUENCY ON CONNECTICUT RIVER SHOWING EFFECT OF INCREASING TWO FLOODS

Mr. Fuller. streams of similar nature in the vicinity should be made. This study should be just as complete and thorough as it would be if any other method of determining the maximum flood were to be used. The use of the average flood facilitates the determination where means are at hand to determine it. The values of *C* in Column 8 of Tables 12 to 26, inclusive, were obtained from published records. These values are useful for comparison, but it should be understood that the accuracy of the measurements of the floods from which they were obtained should be verified before use is made of them. In any event, coefficients are directly applicable only at the point where the measurements were made, or at other places where the conditions are similar.

Before selecting a value for *C* from the average flood, any changes in the river itself or in its catchment area which would affect the value should be studied. Additional storage, congestion of the channel, and other matters may change the flood-producing capacity of a stream, and a value of *C* taken from past floods may not always apply to present conditions.

For rivers on which only short-term records are available, the average flood may be much in error. In order to ascertain the probable accuracy of the average flood, as obtained from records of different lengths, a study has been made of the accuracy of the averages obtained from shorter records on those rivers where long records are available. In this study, use was made of the probability paper devised by Mr. Allen Hazen, and the general method followed was similar to that used by Mr. Hazen in a paper recently presented to the Society.* Details of this method will not be necessary, and only a brief discussion of the method will be given.

For use in the study, records of 15 years or more were utilized. It was assumed that the average of the total records is the true average. The long records were then divided into a number of shorter records, and the average flood, as indicated by these shorter records, was obtained. The ratio of these average floods to the assumed true average flood was found. The ratios thus obtained from all the records of different rivers were combined, on the assumption that the chances for errors on all streams were equal. Plottings were then made of these ratios on probability paper, as shown on Fig. 19. From these plottings Table 44 was prepared, the errors, for 20- and 25-year records being found by extending the curve plotted for 5-, 10-, and 15-year records.

In cases where the value of the coefficient, *C*, is below that of other streams in the vicinity, or where other evidence is at hand to indicate that the coefficient, *C*, is too low, an increase in the value of *C* by at least the probable error would be justified. A further increase

Mr. Fuller.

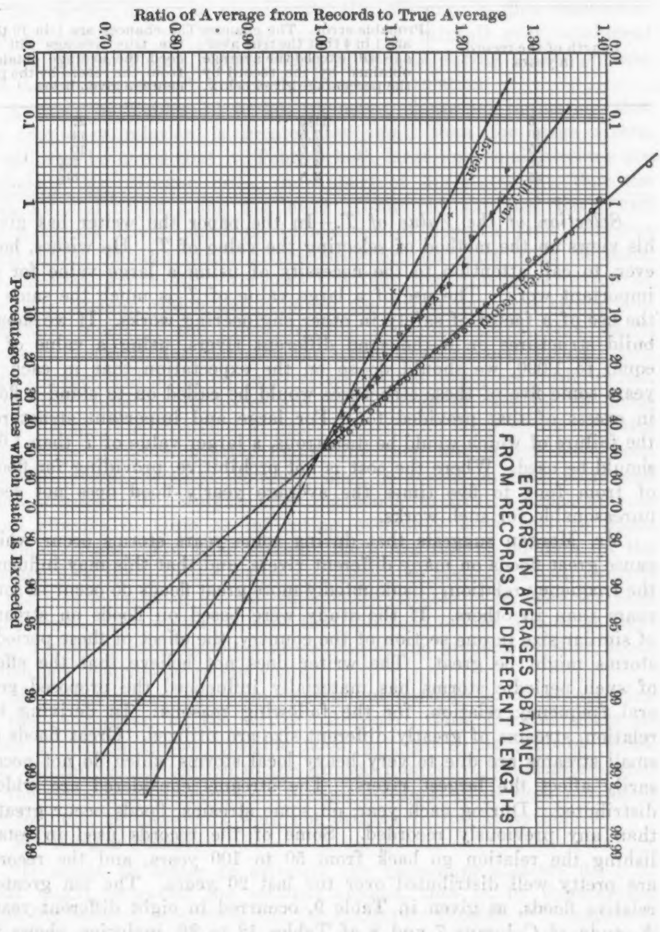

FIG. 19.

Mr. Fuller.

to provide a factor of safety depends largely on the importance of the works under consideration, and on how great a factor of safety has otherwise been provided for in the selection of the value of *T*.

TABLE 44.

Length of the record, in years.	Probable error. The chances are 1 in 4 that the true average will exceed the average obtained by the record by the percentage given below.	The chances are 1 in 10 that the true average will exceed the average obtained from the record by the percentage given below.
5	11½	22
10	7.5	14
15	5.5	10
20	4.0	7½
25	3.5	6½

Selection of the Value of T.—In the paper the writer has given his views on the method of selecting the value of *T*. He wishes, however, to call attention to the necessity of using a large value for all important work. The use of a large value of *T* is much the same as the use of a factor of safety in other engineering works. If we should build structures on a thousand different rivers, using a value of *T* equal to 1 000, we should do so on the expectation that in each 10 years some five of these structures would be called on to stand a flood in excess of that provided for. For large and important structures, the failure of which would be disastrous, a larger value of *T* than 1 000 should be used. Where the cost is not prohibitive, providing for floods of from four to five times the average yearly flood does not seem unreasonable for such works.

Mr. Morgan suggests that during some years storms occur which cause great floods on many different rivers, and that this may influence the frequency relation. Undoubtedly more great floods do occur in some years than in others. If the study were based on floods on streams of similar size in one section of the country, the effect of these periodic storms might be great. The writer does not believe that the effect of such periodic storms has materially influenced the proposed general frequency relation, for the following reasons: In deriving the relation, streams of greatly different size are utilized. Great floods on small streams are due to very heavy local storms which do not necessarily affect the largest rivers. The streams considered are widely distributed. During each year, on some streams, floods occur greater than any previously recorded. Some of the records used in establishing the relation go back from 50 to 100 years, and the records are pretty well distributed over the last 20 years. The ten greatest relative floods, as given in Table 9, occurred in eight different years. A study of Columns 7 and 8 of Tables 12 to 26, inclusive, shows no difference in frequency between streams with long and with short records.

Mr. Morgan states: Mr. Fuller.

"On large water-sheds of 10 000 sq. miles or more, excessive rainfall in one part of the water-shed is usually balanced by lack of rainfall in another part, and the ratio between the average annual flood and the maximum possible flood must be less than for small areas."

The writer does not agree with Mr. Morgan in this statement. The difference in the average intensity of rainfall over catchment areas of different sizes occurs yearly as well as during longer periods, and does not necessarily affect the frequency relation.

A study of Tables 12 to 26, inclusive, shows no indication that the frequency relation is greater for small than for large rivers. It will also be noted that in Table 9 both large and small streams are included. Mr. Morgan cites, in support of his statement, that the large alluvial rivers along the lower Mississippi, the Red River and the Arkansas River, show no indications of deposits from previous great floods, though small rivers elsewhere do show such deposits. Mr. Morgan apparently overlooks the fact that the construction of the levee system, which has confined the floods on these rivers, and prevented much of the great overflow or temporary storage which formerly occurred, has increased the stages during recent floods. Still higher stages will occur on these rivers, as the levees are built higher, until such times as the levees are high enough to care for all floods which occur. The existence of gravel deposits on other rivers indicates past floods of much greater magnitude than any which have been recorded. Such deposits, however, may be found on both large and small streams. Mr. Morgan cites the floods on Devil's Creek and on small streams in Ohio as indicating extremely large relative floods on small rivers. For such streams there are few or no data on the average flood, and, in the writer's opinion, the recorded measurements of the maximum flood are not sufficiently reliable to be used for such comparison. The writer believes that the flood on the Miami at Dayton—a river of considerable size—is one of the greatest relative floods which has occurred in recent years.

Mr. Morgan uses the term "maximum possible flood" as applying to the flood given by the writer's formula. This formula gives no limit to the maximum possible flood, but gives the probable flood. Mr. Morgan calls attention to the limited number of years represented in the table of great floods on foreign streams. This does not affect the formula, as these data were not utilized in its derivation.

Mr. Morgan states:

"It might be better to estimate the maximum possible flood by what might be called the rational method, that is, by determining from the basis of experience and the maximum rainfall to be expected, the relation of rainfall to run-off under the conditions which would exist in an assumed case, considering the elements of topography, shape of the drainage basin, direction of storms, season of the year, etc."

Mr. Fuller.

There is quite as much uncertainty in probable maximum rainfall as in probable flood flow. There is, in addition, great uncertainty as to the percentage of run-off to be expected on different rivers, and under different conditions. We know but little of the effect of topography, direction of storm, shape of catchment area, and other factors. To the writer there seems to be much less chance for error in selecting the value of C from the average yearly flood, or by a study of the values of C for other rivers, than in estimating values for these many unknown quantities.

Many of the important points brought out in Mr. Morgan's interesting and instructive contribution have been covered in the writer's general discussion, and need no further comment.

Mr. Hinckley's interesting remarks, made in 1911, indicate clearly how engineers have looked at the probability of the occurrence of floods. His rainfall data are interesting. The application of probability methods for obtaining the probable rainfall would undoubtedly give much valuable information.

Mr. Chandler presents some valuable data for the flow of the Red River of the North and its branches, and draws some interesting conclusions as to the frequency relation of streams in that section. He says that the conditions in the Red River Valley are similar to those in a partly arid region, so that the writer's average relation does not hold. Although the data available are not sufficient to be conclusive, Mr. Chandler's suggested frequency relation gives an indication of how much higher it may be in such sections. The size of the average flood for such rivers is governed largely by the number of dry years in the period. It occurs to the writer that in determining the average flood, the exclusion from the record of all years so dry that no real flood occurs, may have merits, thus giving an average of the real floods as a basis of comparison. On this basis the relation may be expected to be more like that for other sections.

The writer notes that Mr. Chandler very properly uses the median flood method in his study. This method is better for plotting short records, as the few largest floods do not affect the plotting of the other floods to the same extent as in the average maximum flood method, and by its use a closer approximation to the true curve is obtained.

Mr. Hazen points out clearly the uses and limitations of the proposed formulas. The map of the country (Fig. 8) is most useful, as it indicates the data available for different sections of the country and also shows the variation in the value of C for rivers in the same section. A study of the conditions will in most cases account for such variations. For instance, in Maine, where the coefficients vary from 17 to 110, it will be found that the low coefficients are for small streams draining extensive systems of lakes which control largely the floods, and the large values are for streams on which there is little or no storage.

It is interesting to study the effect of this storage on the river system. For the upper branches, the effect is great, but, as the streams join to form the larger rivers, the effect decreases rapidly until, near the mouth of the river, the coefficients are in some cases several times as great as for the upper branches. The study of streams in that State, where there are such extensive lake systems, is most illuminating in regard to storage for flood protection. Mr. Fuller.

As Mr. Hazen states, probability paper might have been utilized in the study of flood frequency. During the study for this paper the normal probability curve was tried, but it was found that the data did not fit it as closely as the logarithmic curve adopted. The use of probability paper, which provides a ready means of drawing curves varying somewhat from the normal law, allows this method to be used. Practically, however, such a curve would give results identical with the formula, within the limits of the data, and an extension of the curve would indicate a ratio of 4.0 for $T = 10\,000$, as compared with 4.2 by the formula. Such differences are of little moment, and no data are available to indicate which is the more nearly correct.

The method of plotting gauge heights on probability paper, as suggested by Mr. Hazen, should prove useful. The writer has plotted records of the gauge heights for many stations along the Mississippi and its branches. Although these plottings are not in all cases as close to a straight line as the one for Cincinnati, they all approximate such a line. Within such limitations as may be applied by one having a thorough knowledge of the river, both as to changed conditions affecting the stages and as to the storage and increased channel capacity which occur at higher stages, this method seems applicable to many rivers.

Mr. Hazen's suggestion in regard to determining coefficients of variation, as an index of how closely the stream follows the average law of frequency, is interesting. It may be that a thorough study of the regularity of flow throughout the year, and of other characteristics of the stream, would enable the effect of some factors on flood frequency to be ascertained.

Mr. Knowles, citing a record of a single stream as an indication of variation from the average, warns against the general use of the average relation. The writer pointed out in the paper, and has further stated in this discussion, that a thorough study of all local conditions should be made before using the formula, but must repeat that, in his opinion, the data on a single stream are entirely inadequate for establishing a frequency relation. It could be shown by a plotting similar to Fig. 18 that the data for the Allegheny River at Kittanning really differ but slightly from the average relation. Mr. Knowles' extension of the existing record to a 41-year record, by estimating the flood at Kittanning from the gauge height at other points on the river

Mr. Fuller. is of doubtful accuracy. An examination of Figs. 11 and 12 will show that the actual floods which Mr. Knowles plotted in order to obtain the curves showing the relation between the gauge heights at Kittanning and those at Freeport and Parker differ, in some instances, by from 50 to 100% from the curves. If these actual floods do not agree more closely with the curves, it is obvious that similar errors probably exist in the floods obtained in this way and included in the record. As the effect of the few large floods is so important, it is clear that a record obtained by such methods should not be used in discussing frequency.

Mr. Bellamy's discussion is interesting, and gives much valuable information as to flood flows in Australia. The large variation in floods for the different rivers is to be expected in a country so large and with such widely varying conditions. As Mr. Bellamy states, a comparison of such rivers, with the limited data available, is very unsatisfactory. It is much the same as comparing rivers of the American coast, where the coefficients are in many cases greater than 100, with rivers in the Missouri River Basin or the Great Basin, where the coefficients are in many cases less than 10.

Mr. Kuichling has supplied tabulated data relating to great floods which have occurred on both foreign and American rivers, and these, taken in connection with those previously presented by him, give by far the most complete record of maximum flood flows available. The data from which this information was prepared are widely scattered. In many cases, particularly for foreign streams, the original data are in such a state that most careful study of them is required before they can be used. The collection and analysis of this large mass of data should be appreciated by all who are interested in the flood problem.

Mr. Kuichling brings out clearly many important aspects in regard to flood flows. Some of these points have been taken up by the writer in the preceding general discussion, and need no further comment.

Mr. Kuichling calls attention to the wide variation in the value of C for different rivers in the same general section of the country, and suggests that it may be better to use a single value of C for one section. Where coefficients are based on long records, the writer believes that the differences in the values of C indicate different flood-producing capacities for the streams. In many cases these differences may be accounted for by a study of the catchment area, as to slopes, storage capacity in lakes, and rainfall conditions. Where records of considerable length are not available, the writer agrees with Mr. Kuichling that much consideration should be given to the coefficients for other streams in the section. He is correct, in his interpretation of Tables 12 to 26, inclusive, in stating that the values of C in Column 8 were the ones intended for general use. The values in Column 8 are derived from the average flood, and take into account all the largest yearly floods in the rivers; they are more accurate than those in Col-

umn 7. It would have been better, as he suggests, to have called these C_1 and C_2. Mr. Fuller.

Mr. Kuichling calls attention to the important work of Iszkowski, and reduces his formula to conditions for the United States. Although this formula is of very different form from the writer's, it may be of interest to show how the results obtained from it agree with those obtained from the writer's formula,

$$Q \text{ (max.)} = C\, A^{0.8} (1 + 0.8 \log. T)\left(1 + \frac{2}{A^{0.3}}\right).$$

Under what may be regarded as similar conditions, Iszkowski's formula differs from the writer's by the following percentages: for a catchment area of 10 sq. miles, — 21%; 100 sq. miles, + 32%; 1 000 sq. miles, — 2%; 10 000 sq. miles, — 39 per cent. This comparison is made on the basis of the values deduced by Mr. Kuichling from Iszkowski's formula for "hilly country, slightly permeable soil, and sparse vegetation" and of a use of $C = 100$ and $T = 100$ in the writer's formula.

The writer has plotted the largest of the floods in America, as given by Mr. Kuichling, on the lower diagram of Plate XI, and finds that with the exception of three or four extreme floods, such as those on Cane Creek and Devil's Creek, the plottings agree with the curves representing the writer's formula as well as the points previously plotted.

Mr. Horton calls attention to a discussion of the use of probability methods in a report made by Mr. Rafter in 1896. This discussion is interesting and instructive. That paper, however, is entirely confined to a discussion of rainfall and minimum run-off. The writer fails to find any suggestion as to the use of similar methods for determining flood flows. Until Mr. Horton called his attention to it, the writer was not aware of the existence of this study. Mr. Horton further states that Mr. Rafter suggested to him the use of probability methods for determining the probable flood as early as 1896 and that he has used it on numerous occasions in his professional work. The writer had no means of knowing about any work which Mr. Horton had done on this subject, and sees no reason why he should qualify the statement that the original suggestion came to him from Mr. Hazen.

Mr. Horton gives three different formulas derived from the data on rivers near Philadelphia. He also gives the following general formula for which he states that he

"does not claim any great breadth of applicability for the general formula, * * * but believes that factors other than area modify the flood discharge of streams so profoundly that it is better, wherever possible, to derive individual formulas or flood-frequency diagrams for each stream."

Mr. Fuller.

This formula is:

$$Q = 4\,021.5 \frac{T^{\frac{1}{4}}}{A},$$

in which Q is the flow in cubic feet per second per square mile. To put this formula on the basis of the writer's, that is, to give the total flood flow of the stream, it becomes necessary to multiply by A, so that the formula becomes

$$Q = 4\,021.5\ T^{\frac{1}{4}}.$$

According to this formula, the maximum floods to be expected are independent of the catchment area. Surely a formula which does not take into account the size of the catchment area can have no general application.

During the early part of the study for this paper, exponential formulas such as those proposed by Mr. Horton were tried. It was found that though these gave curves closely following the data for short periods, for the longer records the exponential relation was less satisfactory than the logarithmic relation adopted.

The writer deems it unfortunate that, after seventeen or more years of consideration of the use of probability methods for the determination of flood flows, Mr. Horton should have confined his discussion so largely to criticizing details of the writer's methods, instead of giving more in regard to his own studies.

Mr. Horton states:

"It would appear that the relation between flood magnitude and frequency, when expressed in terms of either 'average maximum flood' or 'median flood,' is not only very indefinite and difficult of comprehension, but is apt to be very misleading, if it is not indeed practically meaningless. It does not directly convey the information which the engineer usually most desires, for example: If a spillway has a capacity of 1 000 cu. ft. per sec., how often on an average will its capacity be exceeded?"

In regard to this statement, the writer will call attention to the fact that the others who have discussed the paper have not found the proposed formula either indefinite or misleading, but, on the contrary, have comprehended its true meaning. The writer, on pages 575-582, described three different methods which are applicable to flood frequency problems. In Table 6 the formulas representing these methods are stated, and values are given for the volume of the flood indicated by them in different periods of time. If any one wishes to know the volume of the flood that will probably be equalled or exceeded in a period of time, he may do so by using the formula:

$$Q \text{ (equalled or exceeded)} = C\,A^{0.8}\,(0.7 + 0.8 \log. T)$$

as given in Table 6. There are problems in which it is useful to know the volume of this flood, but the writer believes that the most important question which the engineer desires answered is: What is the probable flood for which to design our structures? For this purpose we surely do not wish to ascertain the smallest of the maximum floods that is likely to occur in the given interval, which is only a different way of stating the "flood to be equalled or exceeded." For example, suppose we have a record which includes ten periods, each of 20 years. Each of these periods would have a maximum flood of a different size. The flood to be equalled or exceeded in a 20-year period would be the smallest of these. To design works which would just provide for this flood would mean that in all probability the design would prove inadequate within the period, because during nine out of ten periods, greater floods would occur. Mr. Fuller.

The average of the ten maximum floods which have occurred in the several periods, as given by the writer's formula, seems to be a logical basis for design in order to provide for a reasonable chance that the structure will survive the given interval. The median of these floods, or the one for which there is one greater for each one less, represents the flood for which the chances are even that it will occur in the given period. The use of this flood is as logical as the use of the average. The difference in value between the two is slight, and the writer, for the reasons stated in the paper, prefers the average maximum.

Mr. Horton, after giving a method of determining the "average interval of recurrence of a flood lying between any two given magnitudes", states: "This illustrates what seems to be a fatal error in the author's method of analysis."

The writer fails to find in the paper any statement which would justify the interpretation Mr. Horton has given the formula. As the method of derivation and the meaning of the formulas are explained in considerable detail in the paper, the writer considers that to apply it as Mr. Horton has done is entirely unwarranted. If the determination of the average interval of recurrence of floods of a size between fixed limits is desirable, as it may be for some special problem, the use of the flood to be equalled or exceeded, as suggested by Mr. Horton, is proper. Such use, however, is an unusual one, and to find a "fatal error" in the average maximum flood formula because it is not applicable to such a problem, is like condemning a formula proposed for determining the strength of a steel beam because it does not give the deflection of the beam. The writer was aware that the "flood to be equalled or exceeded" and the "median flood" had their uses, and accordingly gave the formula by which they might be obtained and descriptions of the methods of derivation, but, to

Mr. Fuller. explain their application to special problems, he thinks is beyond the scope of the paper.

Mr. Horton considers the use of ratios "confusing and cumbersome". By the use of ratios it becomes possible to compare the frequency of occurrence of floods on different rivers, which, in the writer's opinion, is of the greatest importance.

Mr. Horton objects to the writer's method in that he does not use all the floods to determine the frequency relation. As a matter of fact, in the determination of the general formula, 1 672 floods were considered; 20 of the largest were plotted individually and 200 others in groups of ten. This plotting covered three-quarters of the total length of the curve, as plotted in Fig. 1. It is apparent that, with the average maximum method, the average flood, which has a ratio of unity, must be plotted for 1 year. A straight line drawn from unity through the average of the points plotted satisfied the requirements, thus making the plotting of the remaining points so obviously unnecessary that it was not done. The writer assures Mr. Horton that the remaining points will fall close to the line. Mr. Horton's other criticisms of the paper are, the writer believes, fully covered by the foregoing discussion.

Mr. Pillsbury's discussion is an interesting and natural one. An examination of Fig. 18 shows how a slight change in the data on the Connecticut River would affect the frequency relation, and the writer has already given his views on the reliability of frequency relations established from the records of single streams. Aside from this, the assumption made by Mr. Pillsbury contains a fundamental error which would have to be, and could be, eliminated. This error is in assuming that the series of annual floods follows the normal law of probability. By the normal law of probability, the variations upward and downward from the normal are equal. As a matter of fact, with flood data, the variations upward and downward are not equal. The variations downward are more numerous, but the variations upward are greater in magnitude. The values follow, not the curve of normal probabilities, but what is called a skew curve. If Mr. Pillsbury will deduce the formula that most accurately represents this skew curve, and will show its application, he will give a useful solution of the problem which he has attempted, and will be doing the Profession a real service.

Paper No. 1294

CONCRETE BRIDGES: SOME IMPORTANT FEATURES IN THEIR DESIGN.*

BY WALTER M. SMITH, SR., M. AM. SOC. C. E., AND WALTER M. SMITH, JR., JUN. AM. SOC. C. E.

WITH DISCUSSION BY MESSRS. S. W. BOWEN, WILSON FITCH SMITH, C. E. GREGORY, HENRY H. QUIMBY, A. C. JANNI, PHILIP AYLETT, L. J. MENSCH, A. W. BUEL, W. D. MAXWELL, AND WALTER M. SMITH, SR.

It is the object of this paper to bring out several important features in some concrete bridges recently designed by the senior writer.

Reinforced concrete is now being used in the construction of bridges of all three types: arch, girder, and truss; in fact, there is a bridge across the Seine at Avranches, France, which combines all three types: an arch span of 110 ft., two girder spans of 34 ft. each, and a truss span of 100 ft. There are two girder bridges near Pittsburgh, Pa., one of 75, and the other of 67 ft. span. In Nashville, Tenn., there is a railroad bridge which has two 95-ft. spans, consisting of reinforced concrete bowstring trusses.

The great advantage of concrete over stone for bridges is, of course, in its economy. The concrete bridge has an additional advantage in being stronger and much more reliable, due to the absence of joints.

The mortar in the joints of a stone arch is only from one-fifth to one-tenth as strong as the stone, and all the joints are never completely

* Presented at the meeting of November 5th, 1912.

filled with mortar. In arch work it is very difficult to fill completely with mortar an accurately cut joint of considerable area and small thickness. The writers are very strongly of the opinion that there has never been constructed a large stone arch in which every joint was completely filled with mortar. They have seen first-class stone and brick masonry torn down, in which not more than 75% of the space in the joints was filled with mortar. On the other hand, they have often had to excavate concrete (which had not been built with special care, but with a very cheap class of labor) in which there were no voids whatever.

The following is an example of the difference in cost of construction of concrete and stone arches. In the Manhattan anchorage of the Manhattan Bridge in New York City, the cost of the labor alone in setting the stone in arch work was $5 per cu. yd. The stone itself cost about $25 per cu. yd., delivered at the site, therefore the cost of the finished masonry, including cement, was more than $30 per cu. yd. The cost of this arch stone would have been much greater had it not been for the fact that it was included in a contract for a very large quantity of coursed dimension stone masonry, so that the cost of the latter governed the price of the arch work.

In the Rye Outlet Bridge, a reinforced concrete arch bridge of five spans of about 127 ft. each, designed by the senior writer, and built by the New York Board of Water Supply, near Valhalla, N. Y., each arch span, containing about 400 cu. yd., was built in an average of 10 hours. There were about 40 men working 10 hours on each span, therefore there were 400 man-hours on each span, or an average of 1 cu. yd. per man per hour. These men were paid from $1.50 to $1.75 per day of 8 hours. The cost of the labor, therefore, was about $0.22 per cu. yd. The net cost of the materials was about $4.25 for concrete, and $5 for steel, forms, etc., giving a total net cost of about $10 per cu. yd., as compared with a little more than $30 for stone masonry. The actual price of this concrete, including the contractor's profit, was $12.50, and of the stone about $34.00.

There is one case in which the stone bridge is preferable to the concrete. If esthetic features are paramount, and economy is not to be considered, then the stone bridge, on account of its adaptability to architectural ornamentation may be more desirable; yet, even in this

[illegible]

case, with modern improvements in methods of casting the concrete faces and afterward dressing them with pneumatic tools of various kinds, the concrete bridge can be made almost as handsome as the stone bridge at much less than half the cost.

The writers have heard doubts expressed by engineers as to the weathering qualities of tool-dressed concrete faces. There is ample proof that concrete surfaces, if properly proportioned and cast, may be dressed with any kind of tool, and will weather much better than sandstone, and almost as well as granite.

Fig. 1 is a view of the Connecticut Avenue concrete arch bridge, in Washington, D. C., in which the voussoirs of the arches and quoin blocks of the piers are of concrete with a mortar face about 1 in. thick, composed of granite dust and cement, the exposed faces being patent-hammered with a pneumatic tool after thorough setting. In dressing these blocks it was found that considerable time had to be allowed after they were made before they could be cut, as otherwise the dust would stick to the blades of the hammer and be driven up between them, breaking the tool.

In the winter of 1905, when this bridge was being built, the writers were residing in Washington, and paid particular attention to its construction. In the summer of 1910, in passing through the city, the photograph, Fig. 2, was taken, showing the faces of some of the voussoirs and quoins. The tool-dressed faces on these blocks were in perfect condition, and appeared as though they had been dressed only a short time.

This paper is largely a plea for an arch consisting of two ribs, rather than one with a solid soffit; with narrow rather than wide ribs, and with deep ribs of I-section rather than of rectangular section. It is also especially a plea for the three-hinged as compared with the fixed and two-hinged arches.

There are three very important advantages that the three-hinged arch has over the other types. First, in the simplicity and quickness of its analysis; second, in its adaptability to sites where rock foundation is at too great a depth to be reached; and third, the temperature stresses are entirely eliminated.

The abutments or piers of a three-hinged arch may be founded on slightly compressible material without doing any harm whatever,

whereas the slightest yielding in the abutment or pier of a fixed or two-hinged arch is sure to develop cracks in the arches.

As the three-hinged arch is merely two struts pivoted at the springing line and at the crown, and curved to follow the line of the equilibrium polygon, they will rise or fall at the crown to accommodate changes in the length of the struts due to changes of temperature.

If the bridge above the arch has been designed so that the amounts and positions of the loads on the arch ribs are known, a depth of arch rib may be assumed, its weight computed, and a force polygon and pressure line—or equilibrium polygon—drawn for the arch; the arch may then be drawn, and the stresses computed at the various joints. This entire process can be done with a slide-rule in a single day by a competent man. It very seldom takes more than three trials to fix all the dimensions of a three-hinged arch, whereas it will take several days for each analysis of the fixed arch.

The correct center line for the three-hinged arch should be drawn as follows: Assume the arch to have one-half the span fully loaded and no live load on the other half. Draw the equilibrium polygon for both the loaded and unloaded sides, then draw a line for the center line of the arch midway between the two polygons, as nearly as may be, by taking not more than three centers. It is known that the equilibrium polygons for the arch fully loaded and with no load will lie between the polygons for the half loaded and half unloaded sides; therefore, it is known that the center line drawn is for the most extreme positions of the equilibrium polygon. This may be called drawing a pressure line, and building an arch around it, and is the economical way to design an arch, as the writers can testify from experience.

The three-hinged arch has two slight disadvantages as compared with the fixed arch. First, the cost of the hinges; and second, its somewhat awkward appearance on account of the necessarily increased thickness at the haunches. The second of these cannot be avoided, but the saving in concrete in an arch of large span much more than pays for the hinges.

Fig. 3 shows two bridges which are identical in design above the arch ribs: one consists of two fixed, and the other of two three-hinged arch ribs. On Plate XV are shown cross-sections of these bridges. The stresses in the arches of these two bridges are about the same;

CONCRETE BRIDGES.
MISCELLANEOUS DETAILS

that in the fixed arch, however, runs up to almost 10% more than that in the other near the springing line.

The stress from the temperature in the fixed arch here shown is in some places 40% of the total, assuming a rise and fall of 40° Fahr. from the mean temperature. An additional objection to the fixed arch is the uncertainty of temperature stresses. Conservative engineers generally assume a variation of 40° Fahr. each way from the mean. Some, however, assume a total variation of 40 degrees. The writers do not believe this to be good practice, for the reason that the time of the construction of the arches cannot be specified, therefore some may be built in quite cold weather, and others when the weather is warm. In the Rye Outlet Bridge, for example, the first arch was poured in April, when the average temperature was about 50 degrees. This arch, therefore, probably has a variation of about 40° each way from the setting temperature. The last arch was poured about July 1st, when the average temperature was more than 70 degrees. As concrete sets at a temperature several degrees above that of the surrounding air, the probable maximum drop in temperature below that of setting will be about 65 degrees. The other arches range between these two, all of them, probably, having a greater fall than rise. This uncertainty cannot be guarded against, as it is manifestly impossible to specify at just what time of the year the arches shall be constructed. If a bridge is safeguarded against this uncertainty by designing the arches for a variation of 60° each way from the setting temperature, it greatly increases the cost, and renders the three-hinged arch still more economical in comparison.

Fig. 3 shows a fixed and a three-hinged arch. Their construction, with the exception of the arch, is the same. On Plate XIV there is shown a cast-steel hinge for the three-hinged arch, similar to those used in the Traver Hollow Bridge now being built by the New York Board of Water Supply. On the same plate there is shown a granite hinge. The cost of the steel in the hinge would be about 6 cents per lb., and of the bronze pin and lining about 30 cents per lb. The cost of the granite would be about $50 per cu. yd. and the lead about 8 cents per lb. The cost of the concrete for the Rye Outlet Bridge would be about $12.50 per cu. yd. The quantity of concrete in the fixed arch span on Fig. 3 is 380 cu. yd.; that in the three-hinged arch is 200 cu. yd. The difference in cost of the two bridges, therefore, would be:

WITH METAL HINGES.

Fixed arch, excess in concrete, 180 cu. yd. at $12.50		$2 250
Three-hinged arch, steel hinges, 11 000 lb. steel at 6 cents	$660	
Three-hinged arch, bronze pin, etc., 600 lb. bronze at 30 cents	180	
		840
Difference in favor of the three-hinged arch		$1 410

WITH GRANITE HINGES.

Fixed arch, excess in concrete, 180 cu. yd. at $12.50		$2 250
Three-hinged arch, granite hinge, 9 cu. yd. at $50	$450	
Three-hinged arch, sheet lead, 600 lb. at 8 cents	48	
		498
Difference in favor of the three-hinged arch		$1 752

The ribs of this arch are rather too wide for a stone hinge, as it is not good practice to cut a thin stone 9 ft. in length, and it is not desirable to have a joint in the hinge. If the arch rib is wider than 6 or 7 ft., it is better to use a metal hinge; if it is of less width, a stone hinge may be used with advantage, as it is very simple and economical.

When the arch span is 200 ft. or more, there is a decided economy in making the rib of I-section instead of rectangular. By building the rib of this section there is a gain in two ways. A portion of the concrete is taken from along the neutral axis of the arch, where it does the minimum amount of good, and a portion of it is replaced along the upper and lower edges of the rib as flanges, where it will act to much greater advantage. These flanges should not project very far, and the slopes connecting them with the web should be quite steep, so that there will be no difficulty in filling the flanges completely with concrete. The web should be left sufficiently wide to contain two steel ribs, with room between them in which the men may move about in placing and ramming the concrete. This makes the minimum satisfactory thickness of the web about 3 ft. The flanges should not project more than 12 or 15 in. from the web; therefore, with a 3-ft. web, the width of the rib would not be more than 5 or 5½ ft.

The analysis of the rib of I-section is just as simple as that of

rectangular section, except in computing the stress in the outer fibers. On account of the moment of inertia of the I-section being more complicated than that of the simple rectangle, the process of computing the stress at the joints is longer and more tedious.

On Fig. 4 are shown two three-hinged arch bridges with ribs of the same width. In one the ribs are of I-section, and in the other the section is rectangular. The ribs are designed so that the stress in the outer fibers is the same in both cases. The portion of the structure above the arch is the same in each of the bridges. In the arch of the bridge with ribs of I-section there are 420 cu. yd. of concrete; and in the other there are 490 cu. yd. Thus there is a saving of 70 cu. yd. of concrete in the arch of I-section over the other. There will also be a slight saving in the hinges, as the thrust thereon is materially less on account of the concrete in each rib having been reduced 35 cu. yd., or 140 000 lb. There will also be a slight saving in the abutments, due to the same cause. However, neglecting entirely the saving in the two latter cases, the sum saved by building the ribs of I-section is more than $800 for the single span.

The question might be asked: why would it not be better to increase the depth and decrease the width of the rectangular rib, making it as small in area as the I-section, without overstressing it?

The objection to doing this is that the ribs have to be braced at certain intervals; and between the point of attachment of these braces they act as struts. A strut, to be economically designed, should be equally strong in all directions. If the rib, therefore, should be built three or four times deeper than wide, it would be much weaker, acting as a strut, unless the bracing was put in at shorter intervals; the increase in concrete, due to the additional bracing, would counterbalance the saving in the rib, and nothing would be gained thereby; and the arch will not have been as well designed. The bracing was not considered in the comparison of the arches, it being assumed as the same in both cases, as the ribs are of the same width.

Another and most important point in the design of a concrete arch bridge is the shape of the piers. Following out the same idea as in the arch, that is, to get as much of the concrete as possible placed well away from the neutral axis, it is very desirable to build the piers, from a short distance below the springing line, in two separate legs, braced at whatever intervals may be necessary, or, in extreme cases,

connecting them by a thin diaphragm down to where they enter the ground. These legs should be made as thin as the nature of the case will allow, in directions transverse to the axis of the bridge, i.e., in the direction of the axis of the bridge, they [illegible] in order to keep the point of application of the resultant of all forces acting at every point, within the middle third, and also to keep the stress within the desired limits.

In a rectangular pier, generally, if it is desired to keep the line of pressure within the middle third, the stress will not be nearly as great as it is proper to allow, and yet it is not good practice to let the point of application of the resultant lie outside the middle third and thus cause tension in the joints. On the other hand, with the braced pier, one is able, with a little care, to design a pier which will have the line of pressure within the middle third, and also have the stresses about the figure desired, thereby attaining a pier of maximum economy.

On Plate XV there are two piers illustrating this point. The first is a braced pier somewhat similar to those in the Big Outlet Bridge. From a short distance below the springing line the pier consists of two separate legs, braced at two points. This pier is of about the same height as two of the piers in the Big Outlet Bridge. The second is an ordinary solid pier of rectangular section of the same height. Both piers are designed so that the pressure line is at the middle third point of all joints. On comparing these two piers it will be seen that the stresses in the braced pier remain quite uniform, except near the bottom, where they increase a moderate amount. In the upper part of the rectangular pier, however, the stresses are too low for economy, and yet it is not desirable to increase the stress by allowing the pressure line to go outside the middle third and cause tension in the joints. The difference in the quantity of material in these two piers is surprising; the braced pier has only 1 785 cu. yd. of concrete; the solid pier has 2 825 cu. yd., a difference of 1 040 cu. yd., or 58% of the braced pier and 37% of the solid pier. The difference in cost of the two piers, therefore, is about [illegible]. The braces in the pier, however, are of reinforced concrete, which tends to decrease the difference somewhat; but, on the other hand, if the earth excavation is deep, and within a cofferdam, there will be much less excavation for the braced than for the solid pier, which increases the difference in the cost. Piers of this shape are not handsome, but if economy is

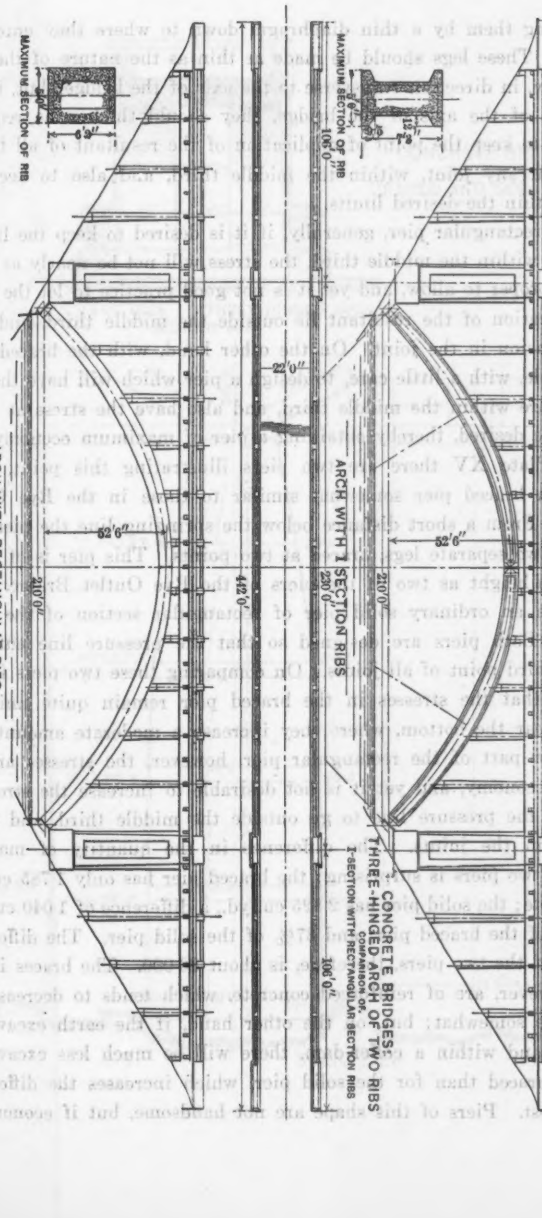

FIG. 4.

connecting them by a thin diaphragm down to where they enter the ground. These legs should be made as thin as the nature of the case will allow, in direction transverse to the axis of the bridge; but, in the direction of the axis of the bridge, they should thicken as required in order to keep the point of application of the resultant of all forces, acting on any joint, within the middle third, and also to keep the stress within the desired limits.

In a rectangular pier, generally, if it is desired to keep the line of pressure within the middle third, the stress will not be nearly as great as it is proper to allow, and yet it is not good practice to let the point of application of the resultant lie outside the middle third, and thus cause tension in the joint. On the other hand, with the braced pier, one is able, with a little care, to design a pier which will have the line of pressure within the middle third, and also have the stress at about the figure desired, thereby obtaining a pier of maximum economy.

On Plate XV there are two piers illustrating this point. The first is a braced pier somewhat similar to those in the Rye Outlet Bridge. From a short distance below the springing line the pier consists of two separate legs, braced at two points. This pier is of about the same height as two of the piers of the Rye Outlet Bridge. The second is an ordinary solid pier of rectangular section of the same height. Both piers are designed so that the pressure line cuts the middle third point of all joints. On comparing these two piers it will be seen that the stresses in the braced pier remain quite uniform, except near the bottom, where they increase a moderate amount. In the upper part of the rectangular pier, however, the stresses are too low for economy, and yet it is not desirable to increase the stress by allowing the pressure line to go outside the middle third, and cause tension in the joints. The difference in the quantity of material in these two piers is surprising; the braced pier has only 1 785 cu. yd. of concrete; the solid pier has 2 825 cu. yd., a difference of 1 040 cu. yd., or 58% of the braced pier, and 37% of the solid pier. The difference in cost of the two piers, therefore, is about $6 000. The braces in the pier, however, are of reinforced concrete, which tends to decrease the difference somewhat; but, on the other hand, if the earth excavation is deep, and within a coffer-dam, there will be much less excavation for the braced than for the solid pier, which increases the difference in the cost. Piers of this shape are not handsome, but if economy is

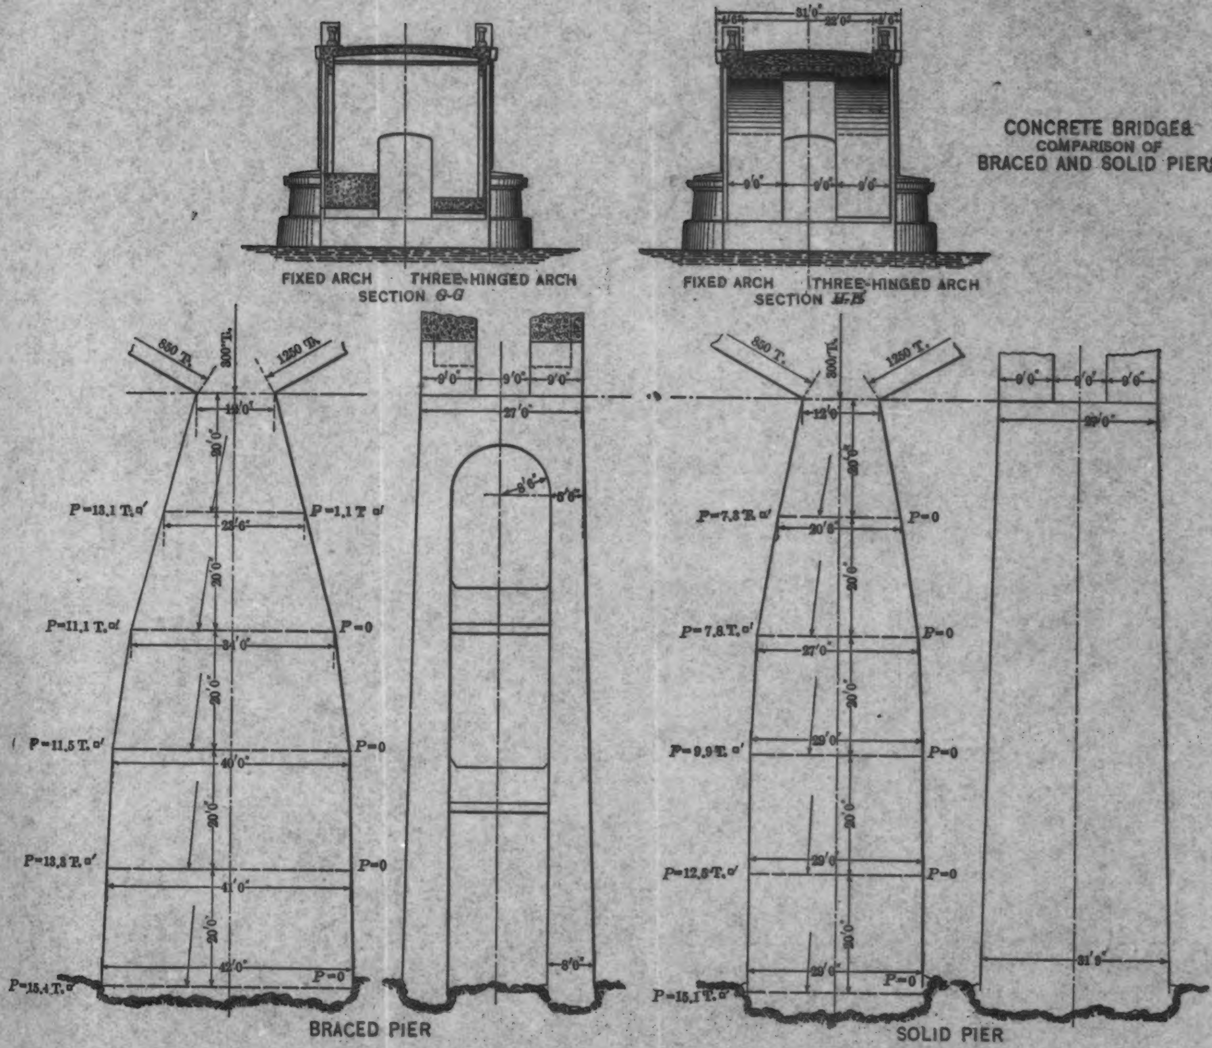
SMITH ON
CONCRETE BRIDGES.

CONCRETE BRIDGES
COMPARISON OF
BRACED AND SOLID PIERS



an important consideration, they are very desirable; and if they are to be hidden by the water from a short distance below the springing line, as in the Rye Outlet Bridge, they will not detract from the appearance.

This type of pier is especially economical for a bridge in running water in which there is likely to be heavy blocks of ice or logs of wood moving rapidly. By putting a cut-water on the up-stream side to deflect such objects, and spreading the legs of the pier rapidly and connecting them with a thin diaphragm, the bridge can be braced thoroughly with very little additional masonry in the piers. In a very cold climate, where heavy ice is likely to form about the piers, the connecting diaphragm should contain steel reinforcement.

In all the bridges on the accompanying illustrations the width is the same; therefore a comparison of the quantity of concrete per linear foot of arch gives a fair idea of the economy of the arches alone. The quantity of arch concrete per linear foot of span in each of the bridges shown is as follows:

Fig. 3, fixed arch, ribs 9 ft. wide	3.00 cu. yd.
Fig. 3, three-hinged arch, ribs 9 ft. wide	1.57 " "
Fig. 4, three-hinged arch, rectangular ribs, 5 ft. wide	2.33 " "
Fig. 4, three-hinged arch, I-section ribs, 5 ft. wide	2.00 " "

From this it is seen that, with the narrow ribs, although the abutments are 50% farther apart, there is very little more concrete per linear foot than in the shorter three-hinged arch with ribs 9 ft. wide.

The writers think that the following conclusions are amply justified by the foregoing comparative investigations:

First, that an arch span consisting of two separate ribs is more economical than one with a solid soffit, if the span is greater than 100 ft.

Second, that narrow, deep ribs are more economical than thin, wide ones.

Third, that the three-hinged arch is more economical and reliable than fixed or two-hinged arches for spans greater than 100 ft.

Fourth, that for spans of 200 ft. or more, the rib of I-section is more economical than the rectangular rib.

Fifth, that piers of any considerable height are much more econom-

ical if built of two separate legs thoroughly braced, thickening rapidly in the direction of the axis of the bridge as they go down.

All numerical computations have been omitted herein, as all the processes of investigation are simple, and it was not desired to lengthen the paper by including them.

The ratio of the modulus of elasticity of steel to concrete was taken as 15, and in obtaining the moment of inertia of the sections at the various joints the steel was considered as being replaced by 15 times its area of concrete.

The Rye Outlet and Traver Hollow Bridges were constructed by the Board of Water Supply, consisting of Messrs. Charles Straus, Charles N. Chadwick, and John F. Galvin. J. Waldo Smith, M. Am. Soc. C. E., is Chief Engineer and A. D. Flinn, M. Am. Soc. C. E., Department Engineer, Headquarters Department, in charge of all design. Charles E. Gregory, M. Am. Soc. C. E., was Designing Engineer in Charge of Design of Dams and Bridges, and the senior writer had charge of the design of the Rye Outlet Bridge and the preliminary design of the Traver Hollow Bridge under Mr. Gregory.

DISCUSSION

S. W. BOWEN, M. AM. SOC. C. E. (by letter).—The writer is much interested in this paper, especially in that portion relating to three-hinged ribbed arches. The comparisons of cost of the three-hinged and fixed types seem to indicate that the former is not such an expensive form of construction as we are sometimes led to believe. The comparison, however, is incomplete, as the cost of the rib reinforcement is not included. A fair comparison of the two types cannot be made without including this item. Mr. Bowen.

As pointed out by the authors, the three-hinged arch possesses a number of advantages over the fixed type, not the least of which is the certainty and simplicity of the calculations. One cannot carry through even the more simplified theories of fixed-arch design without being impressed by the length and complicated nature of the computations involved. These computations are based on assumptions which may not be strictly correct and may be entirely upset by a slight movement of one of the supports, to say nothing of the complications caused by temperature. In comparison with this, there is little, if any, uncertainty in the design of a three-hinged arch. The computations are simple, and the stresses in the ribs can be ascertained as accurately as the dead and live loads.

In some reinforced concrete viaducts, designed recently by the writer, cast-steel hinges having hemispherical, ball-and-socket joints were used. The price paid for these castings was 7 cents per lb. in place, which is high. Even at this price, the cost of the hinges amounted only to about $3\frac{1}{2}\%$ of the cost of the structure. This does not seem to be an extravagant price, considering the many advantages obtained. The writer believes that more can be gained by developing a cheap form of hinge than by producing new theories of fixed-arch design.

With reference to the ribbed type, as compared with the solid arch ring or barrel type, the former has one advantage over the latter which is not brought out by the authors: This is the fact that no water-proofing is required where ribbed arches are used. Water-proofing is frequently an expensive and troublesome proposition, and the type of construction that does away with it is worthy of consideration for that reason alone.

As to the I-shaped section for the ribs of long spans, it is doubtful whether this cross-section is much more economical than the rectangular section. The forms for the former will be more expensive per cubic yard of concrete than those for the latter, and the cost of placing concrete in the I-section will be greater per cubic yard than in the rectangular section. This will tend to reduce the difference in cost due to the smaller yardage of concrete in the I-section.

Mr. Bowen.

In conclusion, the writer wishes to state that he agrees fully with the authors as to the advantages of the three-hinged ribbed arch over other types of arch, and believes that this valuable paper will do much toward bringing this type into more general use.

Mr. W. F. Smith.

WILSON FITCH SMITH, M. AM. SOC. C. E—Referring to the authors' arguments in favor of the three-hinged arch and the subsequent discussion of its merits, it may be of interest to recall the masterful way in which the late George S. Morison, Past-President, Am. Soc. C. E., used the principles of arch design by applying the theory of the three hinges to a masonry arch of long span.

In 1900 Mr. Morison designed a masonry highway bridge of five arches, each with a span of about 180 ft. The arches were circular segments having a rise of one-quarter of the span. The bridge was 80 ft. wide and the arches extended for its full width. The arch ribs varied in depth from 5 ft. at the crown to 7 ft. at the springing line, and were to be of limestone with voussoirs of full depth on the faces of the arches. The arch rings carried cross-walls 4 ft. thick, spaced about 15 ft. apart, which, in turn, carried full centered arches supporting the floor, except at the three center panels where the spandrel was carried up solid to the floor level. At the crown joint and springing line joints were inserted lead bearings, about 1 ft. wide at the crown and 18 in. wide at the end joints. These plates were to act as hinges, permitting an adjustment of the arch under the dead-load strains, and the joints were to be filled with cement mortar after the completion of the bridge.

In the design of these arches the usual method was followed of dividing the arch ring into short sections, considering the weight of each as acting in a vertical plane through the center of gravity of each section. The weight of the spandrel arches and flooring was divided in a similar manner. The strains were determined graphically, and by leaving voids of various sizes in the concrete filling over some of the spandrel arches and loading others with pig iron embedded in the concrete, an arrangement of loads was obtained which produced a resultant curve of pressure passing through the center line of the arch ring at each panel point under the cross-walls and at the hinge joints.

For various conditions of live load, the arches were considered as fixed (the hinge joints being filled before admitting traffic) and the resultant lines of pressure lay well within the middle-third of the arch rings, giving very moderate pressures for such large spans.

This treatment, in its simplicity and the skillful use of the three-hinge theory, is an example of the clear-sighted manner in which Mr. Morison approached problems of design, and shows the attributes of the great engineer.

C. E. Gregory, Assoc. M. Am. Soc. C. E.—The speaker was the Designing Engineer in charge of the design of bridges built by the Board of Water Supply, as referred to in this paper, and wishes to make a few statements to amplify the relation of the work as done by the Board of Water Supply to this paper, and to put others who were concerned in the design of these bridges in a right position in regard to it. The first point he desires to make is this: Mr. Gregory.

The authors reach the conclusion that in practically all cases the three-hinged arch is more economical for long spans than the ordinary fixed-end arch. When designing the Traver Hollow Bridge, the speaker did not, and does not now, concur in such a conclusion. The three-hinged type was selected largely because of expected slight settlement in the foundations, rather than the economy of the type of bridge. The preliminary estimates indicated that a three-hinged arch would be more expensive than a fixed-end arch.

The economy of the divided pier is brought out by the authors, but the manner in which the design of the piers of the Rye Outlet Bridge was arrived at differed considerably from that described in the paper, although meeting the assumptions of the authors. The interesting and unusual feature of this bridge is that it is an arcade of five reinforced concrete arches supported on exceptionally high piers. It was found that the yielding of the top of a high pier of ordinary shape under the unbalanced live load arch thrust (the height of the highest pier in this bridge being a little more than 100 ft.) would be sufficient to create considerable stress in the arch without exceeding the usual limits of stress or creating tension in the pier. The design was made to limit the yielding of the piers to that which could be safely and economically provided for in the arches. The entire arcade was treated as a complete elastic structure, and determination was made of what proportion of the unbalanced thrust from a loaded arch would be carried by the adjacent pier and by other arches and piers of the arcade. The shape and size of pier adopted was found to be necessary from calculations made as just outlined.

This work was done under the speaker's supervision by Mr. George L. Bennett and Orrin L. Brodie, M. Am. Soc. C. E., who were at the time assigned to Mr. Smith's staff, but worked on this problem under the speaker's immediate direction.

Henry H. Quimby, M. Am. Soc. C. E.—Experience in the design of concrete arches confirms the opinion expressed by Mr. Gregory regarding the relative economy of fixed and hinged rings, and the justification for the use of hinges. Computations for comparison of designs in several cases have failed to show any saving in cost of a three-hinged type over a fixed type when the ratio of rise to span was fairly good. Hinges are justified only when the foundations are unsatisfactory, or in cases where the arch is very flat. In Mr. Quimby.

Mr. Quimby.

a flat arch the crown movement due to change in length of ring from temperature is greater than in a high-pitched one, and the temperature stress may thus become great enough to warrant the use of a hinge to avoid it. The arches shown in the paper, however, are not flat, but have a good rise.

The authors give estimated quantities of concrete required for the arch rings in the two designs shown, and represent the fixed type as requiring 90% more concrete than the hinged. This is hard to understand. A fixed ring should require only a little more than a hinged ring. The depth at the crown must be about the same for each because the horizontal thrust is about the same, and any theoretical eccentricity, due to unsymmetrical loading, in the fixed ring will probably be fully matched by the effect of friction of the hinge in the other case, for the inevitable deflection caused by the weight of the floor imposed after the closure of the arch will be likely to produce the effect of eccentric thrust. At the quarter points the hinged ring will need considerably more depth than the fixed ring, and it will be only at the springing line that the fixed ring will be deeper and require more concrete. As the cost of effective hinges is quite considerable, the net result is generally the reverse of that reported in the paper.

If it be said that the greater depth of the fixed ring design in the paper was made because of temperature stress, the reply is that temperature stress necessarily increases with the depth of the ring, and adding to the depth because of such stress is somewhat like piling a load on a horse's back to enable him to pull a heavier wagon—the poor legs may be overtaxed.

It would seem, therefore, that there must be something wrong, either with the estimates or with one of the designs.

The stone hinges shown in the paper give the impression of being likely to develop friction if they work at all, and this will entail eccentricity of stress in the arch ring, to that extent detracting from the only advantage of the hinge.

The matter of appearance of an arch is important in many places, and the bulging at the quarter that is characteristic of the ordinary hinged ring is distinctly ungraceful and displeasing to the miscellaneous eye which cannot understand the reason for it, while the eye of the designer who knows that the point of greatest shear is the point of greatest single stress, desires to see the arch thickest at the spring where that stress is the greatest.

One very important consideration in a discussion of stress in a masonry arch is the method of construction, and it is generally far more vital than temperature fluctuations. The old-fashioned method of laying up an arch ring from the springing line to the crown, with the attendant progressive deformation of the centering and consequent cracking of the earlier portion of the ring practically reduces the work-

ing thickness of the ring to a fraction of that designed, and may be the real cause of some failures that have occurred. The proper way to avoid cracks or initial stresses in the arch ring due to settlement or compression of the centering during construction is to build the ring in voussoir blocks with narrow key spaces between them. Then when all the blocks are made, and the centering has, therefore, nearly its full load, after the blocks have seasoned and shrunk, cast the keys. Of course, if the arch is small enough to permit the casting of the full length of the ring in one day—say within 10 hours—the separation into blocks will not be needed, because the first portion cast will be still plastic enough when the ring is closed to adjust itself to the deformed centering. It is impracticable to eliminate initial stress wholly, for any of the dead load that is added subsequently to keying will cause some deformation of the ring and consequently initial stress somewhere; but this should never be enough to be serious. **Mr. Quimby.**

The claim advanced in the paper that concrete will weather better than good sandstone, and almost if not quite as well as granite, is hardly to be expected from an experienced observer of concrete work. If the authors know of any formula that will produce concrete with such a desirable quality, they should give it to the Profession. It is a poor quality of building stone that will not hold its surface and its edges better than the best concrete. The statement in the paper sounds a little over-enthusiastic. The friends of concrete will promote its use more effectively by avoiding extravagant claims for it.

Another point in the paper that seems not entirely clear is the claim of marked advantage in the I-shape of arch rib. The arch ring is a column—not a beam. If the curve be true and the line of thrust be central, there is absolutely no beam action. Of course, the width—horizontal thickness—of the rib, and its depth or vertical thickness, should both be theoretically adjusted to make a column that will fail by crushing rather than by buckling, and this will require some minimum width. As regards lateral buckling, any given width is as effective at the mid-depth as at the flanges, and, in any case, suitable transverse bracing should be provided. The method of estimating the saving due to the coring out of the concrete at the sides is hardly fair, because a very large part of the cost of such concrete is in the support of it, and any increase or decrease in quantity will be proper to be charged at only the cost of the material and placing. Besides, the extra cost of the additional form work necessary for the paneling will materially reduce the seeming economy in material.

Replying to the question of a member as to the observed actual range of temperature in concrete arches: Two bridges, constructed within the past 5 years, with electrical resistance thermometers embedded at the mid-line, show temperatures in the concrete ranging far less than is usually assumed. The depth of embedment in one case

Mr. Quimby. is 2 ft. 6 in. and in the other, 4 ft. 9 in. The former is a spandrel filled arch and the other is an open spandrel. The maximum range of temperature recorded thus far has been from 31° Fahr. in winter to 73° in summer, and measurements of change in elevation of crown made at the same times show a rise and fall computed to correspond to a change of temperature throughout the arch ring of 45° Fahr. between the extremes of cold and heat.

Mr. Janni. A. C. JANNI, M. AM. SOC. C. E.—The statement, among others, made concerning the quickness, simplicity, and certainty of the design for three-hinged arches, deserves careful investigation, and should not be accepted off-hand, or as a matter of course.

Therefore, it is not without interest to recall what both theory and experience teach with reference to the equilibrium of this particular kind of construction, and to ascertain to what extent a designer may trust his results.

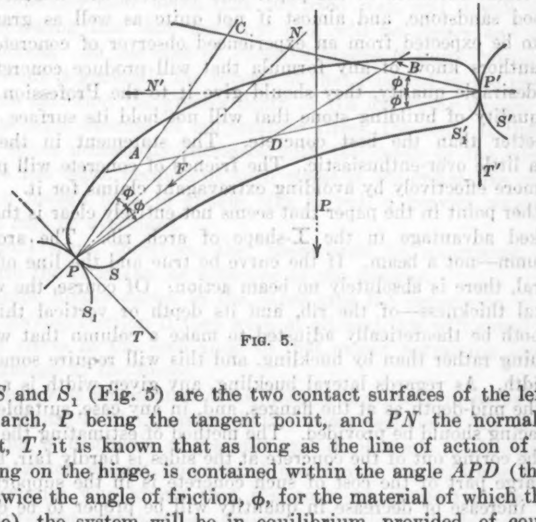


FIG. 5.

If S and S_1 (Fig. 5) are the two contact surfaces of the left hinge of an arch, P being the tangent point, and PN the normal to the tangent, T, it is known that as long as the line of action of a force, F, acting on the hinge, is contained within the angle APD (this angle being twice the angle of friction, ϕ, for the material of which the hinge is made), the system will be in equilibrium, provided, of course, the force, F, is a compressive one with respect to the tangent, PT. Similar remarks may be made regarding the surfaces, S' and S_1', of the hinge at the key.

Therefore, as long as the two components of a force, P, acting on the system, will keep within the two angles, APD and $BP'D$, the system itself will be in equilibrium, and the points, A and B, are to be regarded as the extreme limits of this equilibrium position.

In other words, the system will be always in equilibrium under the action of any force the line of action of which cuts the area, $ACBD$. Mr. Janni.

The foregoing demonstration is very plain, but its foundation is rather indefinite; in fact, it is all based on the assumption that the angle, ϕ, is a known quantity, and, even if that is true, there are two solutions, according to the theory, that satisfy the conditions of equilibrium and, especially for an arch of large and flat span, give quite different results.

Concerning the friction laws, it can be said that, outside of those values of ϕ reported in all engineers' handbooks, which for every-day purposes are tolerably reliable, those laws are not well known at present.

The history of the researches on friction is very brief. Amontos, in 1699, started for the first time a research on the friction of some machine of his, without, however, throwing any important light on the general matter.

In 1781, Coulomb took up the researches on this important problem and announced to the world his results, giving out laws on friction, as well as values of ϕ for different materials.

In 1785, Vince started his researches on the same question and rejected, as unreliable, Coulomb's laws and values of ϕ.

In 1829, G. Rennie, who made tests under about the same conditions as Coulomb, found more or less similar results.

Finally, in 1831, Morin presented before the "Académie des Sciences", in Paris, the results on his friction tests, and, though he confirmed Coulomb's fundamental laws, he found numerical values for ϕ which were very different. It is worthy of note that, though Morin made his tests on a larger scale than Coulomb, he did not go farther than a pressure of about 5.2 lb. per sq. in.

As far as the speaker knows, these are the only works on the subject which stand high on account of the illustrious names of their authors; unfortunately, they do not agree among themselves.

Modern investigations, however, without adding anything definite, have found that the friction law, as given by Morin,

$$R = fN$$

where: R = Resistance due to friction;

N = Normal component of the force acting on the body; and

f = A numerical coefficient depending on the materials in contact;

is not complete; because, though f is dependent on the materials in contact, it is dependent also on the speed with which one surface moves on the other and on the intensity of the acting force; these laws, however, have not yet been determined.

Mr. Janni. The only thing known at present is that the value of ϕ, at the start, is between 1.5 and 3 times its value during the movement, and this is quite a wide range when one considers the certainty of results.

Usually, the hinges are metallic, or, even in stone, they have a shape which might be regarded as a hinge; the problem then is solved, as is well known, in the following manner:

Let A (Fig. 6) be the left hinge of an arch; drawing the friction circle with the radius r sin. ϕ (where r is the radius of the hinge and ϕ the angle of friction), it is known that all forces having lines of action which cut that circle will not move the hinge about its center, and all forces having lines of action tangent to that circle will be on the limit position of equilibrium, provided each of these forces has a tendency to compress the hinge against its groove.

If B is the hinge at the crown, it is known that the four common tangents to the two friction circles are limit positions of equilibrium, therefore, according to graphic statics, the problem already admits of four solutions.

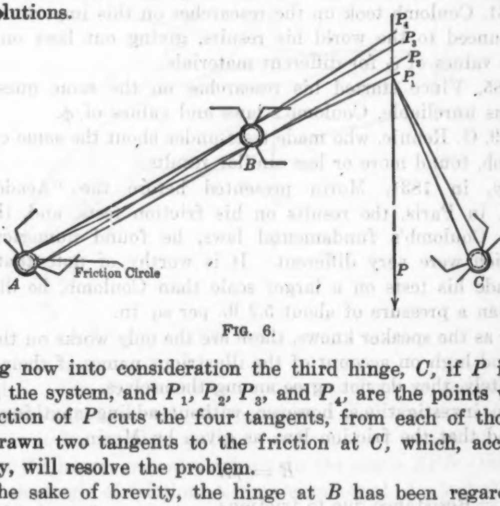

FIG. 6.

Taking now into consideration the third hinge, C, if P is a force acting on the system, and P_1, P_2, P_3, and P_4, are the points where the line of action of P cuts the four tangents, from each of those points can be drawn two tangents to the friction at C, which, according to the theory, will resolve the problem.

For the sake of brevity, the hinge at B has been regarded as of the same kind as those at A and C.

Apart from the several solutions given by the theory on the equilibrium of this kind of construction, here, too, the indeterminations, resulting from friction, must be considered.

The friction circles can be drawn quite accurately for machinery, or when it is a question of pieces well prepared for laboratory tests, for which test after test has been made so that the whole question is somewhat settled.

Concerning the friction in bridge hinges actually in operation, however, on which the pressure is often so great as to wear off the material at the contract surfaces, it is to be said with regret that there has not been a single test known to the speaker. Mr. Janni.

It can be seen, therefore, that the quantity, r sin. ϕ, has not, by any means, a known and determined value; in fact, it is rather arbitrary. In other words, the set of four points, P_1, P_2, P_3, and P_4, can be substituted for another set of four points, provided they satisfy the requirements of graphic statics.

Although all the stated indeterminations (and there are others) do not prevent a designer from patching up some kind of design for a three-hinged arch, it is not possible to accept the statement concerning the reliability of such design.

The hinges, however, in a concrete or masonry arch can be used with advantage sometimes during the construction of the arches, when there is no steel reinforcement to take up the tension at the springing line and at the key, due to a possible excessive settlement of the centering; then, after the centering has been removed, the hinges should be concreted. Thus the arch behaves as a three-hinged arch, as far as the dead load is concerned, and as a rigid arch for the live load and temperature. In that instance the hinges, free from the enormous pressure of the dead load, can easily accompany any movement of it, being concreted afterward, when their behavior begins to be extremely doubtful.

The granite railroad bridge at Morbegno, Italy, with 229.65 ft. span and 32.8 ft. rise, has been built in accordance with the foregoing method.

In comparing concrete and stone bridges, the authors rightly state that one of the advantages of the former is that it is stronger and much more reliable, because of the absence of joints; therefore it is not clear why the paper is a special plea for the three-hinged arch, which has three joints, as compared with the rigid arch, which has none.

Concerning the statement that the trial design for a fixed-end arch takes several days for each analysis, it can be said that it takes no longer than the trial design for a three-hinged arch, and possibly less.

The stresses in the arch with fixed ends, due to dead load and temperature, can be calculated in a day's work easily.

A new method of designing an arch, based on the rather recent theory of the "Ellipse of Elasticity", is described in a paper by the speaker.* This is a purely graphical method and holds, irrespective of the geometrical form of the axis of the arch, irrespective also of the law of variation of the cross-section of the latter, and of the assumptions of loading. In other words, it is possible, by that method, to draw the lines of influence for moments, for any section

* *Journal*, Western Society of Engineers, May, 1913.

Mr. Janni. of the arch, before the loads are applied on the arch, and, as a consequence, the most prejudicial hypothesis of loading for the chosen section is given at once, without any trial.

In that paper, in addition to the theoretical part, the speaker showed a practical application to an arch which he had designed and built by that method.

In contrast with the unreliability of the results in a design for a three-hinged arch, it is not without interest to relate that for a fixed-end reinforced concrete arch, built in France, having a span of 318 ft., the difference between the stresses calculated and the actual stresses reached a maximum of 14.7 per cent.

Every engineer fully appreciates the importance of these results, especially when he considers that, in steel bridges of the best design, that difference reaches 25%, and, when designed on the assumption that there is no friction at the joints, the difference may be more than 100 per cent.

The horizontal thrust, due to temperature changes, is directly proportional to the coefficient of expansion, to the change of temperature in degrees, to the modulus of elasticity of the material, and to the span (measured at the spring points of the geometrical axis of the arch); but it is inversely proportional to the inertia moment of the whole elastic arch with respect to the horizontal (if the arch has its spring points at the same level) passing through a certain point called the center of gravity of the elastic arch.

If, for the same span, arches with different rises are drawn, it can be seen that, although the factors directly proportional to the horizontal thrust remain unchanged (the variation of the span of the geometrical axis may be disregarded), the moment of inertia of the arch increases rapidly with the increase of the rise of the arch; so that the effects of a change in temperature diminish in importance with the increase of the rise.

The shrinkage of the concrete due to setting and that due to the dead load are two important causes of stress to be taken care of, especially the former. If the arch is very flat and has a large span, the best and most economical way to take care of the shrinkage due to setting is by neutralizing its effects, as much as possible. A span of 170 ft. with 17 ft. rise, and two spans of 140 ft. with 14 ft. rise, designed by the speaker, have been built, breaking the arches into voussoirs each about 20 ft. long, and leaving between each two consecutive voussoirs a small voussoir, or key, of 2 ft. The voussoirs were cast first and the keys were not cast until the last concrete of the voussoirs was 10 days old, thus avoiding, for the 170-ft. span, for instance, important tensions on the intrados at the key and on the extrados at the springing line, especially during the winter, due to a shortening

of $\frac{1}{8}$-in. of the geometrical axis of the arch, which otherwise would have taken place. Mr. Janni.

If, as the authors state, an average pressure of 12 000 lb. per sq. in. on the crown hinge of that arch was calculated, it must be inferred that the maximum pressure on the hinge was about 24 000 lb. per sq. in. at the theoretical point of contact with its groove, and it may be assumed that it was reduced to zero at each end of the groove.

The question then arises: At such a vital point of a bridge may the material be submitted to work at a rate which is never allowed for such material at other much less important points; and that without discussing the practical inadvisability of trusting on a $2\frac{1}{2}$-in. space the stability of such a comparatively enormous mass of material?

In dealing with such pressures, however, there is no longer any question of the possibility of assuming that at that point there is a hinge, ready to work; it is no more a matter of design, but of guesswork.

When a hinge of such small diameter is placed at the key, a malicious attempt to wreck the span could be successfully carried out.

Another kind of hinge—fortunately, very seldom used—is a ball-and-socket joint of cast steel consisting of a hemispherical protuberance fitting into a hemispherical cavity. Any horizontal displacement of the crown of the arch, for a structure of this kind, cannot be contemplated seriously; there is no reason for using such a hinge. In the construction of a three-hinged arch, the use of a ball-and-socket hinge means simply the addition of more friction at that joint.

Having an arch with only two ribs, and that arch hinged with the ball-and-socket type, then, at each joint cross-section there will be at least two hinges. Admitting, for the moment, that a horizontal displacement of the crown might take place, it will be admitted also, that it will be very small.

On account of the rigidity of connection between the two ribs, however, there is no possibility of a horizontal rotation of both hinges, even disregarding friction and admitting, of course, the elastic deformation of the whole system; but the effect of that displacement will be only to decrease the pressure on one hinge at the expense of the other.

However, as the use of a hinge of that kind shows that the designer assumed the possibility of a really tangible horizontal displacement of the key and the consequent horizontal rotation of the hinge, it is not without interest to ascertain what would happen to the arch if a horizontal rotation took place at the key, no matter how small it might be, provided, however, that it be a tangible quantity.

Assume that the hinge has a horizontal rotation of only 10′, and that the two hinges are 30 ft. apart; then, while one hinge presses in its socket during a rotation of 10′ (always disregarding friction), the other would be lifted out of its socket a distance of about 1 in. Although

Mr. Janni.

this will not happen, on account of the elastic deformation of the system, it is fair to admit that, at that joint, the horizontal thrust is zero (without speaking of the pressure concentrated on the rotating hinge).

What happens at the key, according to the designer's assumption, will happen also at the springing line, but the order will be reversed. Then the question arises: Did the designer calculate the stresses in his elastic system under such abnormal conditions of equilibrium? If he did, it is certain that he will never advocate the ease, speed, and certainty of a design for a three-hinged arch, especially with ball-and-socket joints; if he did not, then his enthusiasm for structures of this design is quite natural.

M. Mesnager, wisely concerned about the secondary stresses arising from the use of the hinges in arch bridges, and for which there is no way, at present, to determine their exact amount, thought that a half-rigid joint "semi-articulation", the working behavior of which could be easily determined, would be preferable to the usual hinges.

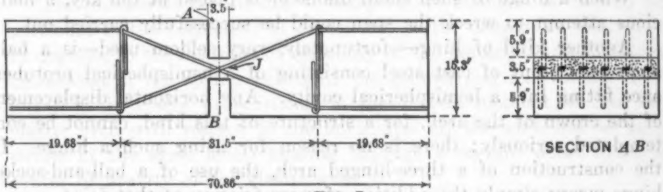

FIG. 7.

For that purpose, several years ago, under his personal supervision, the Testing Laboratory of the "École des Ponts et Chaussées" started researches on a joint, Fig. 7, built in reinforced concrete according to his plans. Without going into details concerning his tests, it is enough to repeat one of his remarks:

"Le moment qui a été nécessaire pour fair fléchir la semi-articulation quand elle était noyée dans le béton, n'était pas négligeable."

Then he concluded by saying that it was possible, perhaps, to free the joint, J, from concrete and fill the remaining space with some kind of non-acid asphalt.

Evidently, a hinge of this kind, if developed properly, could not be expensive, and, at the same time, would eliminate the secondary stresses depending on friction, at least.

Concerning the saving of material by building the ribs of I-shaped section, it may be remarked that such a saving, in a general way, does not mean, necessarily, a saving of money. It would be rather absurd to think that a marble statue costs less than a block of the same material having the same external dimensions, only because the actual volume in the statue is less than that in the block. In addition, how-

ever, to all doubts expressed by other speakers concerning the cheapness of an I-shaped rib, as compared with the rectangular rib, another remark may be made: The three-hinged arch, on account of its lack of rigidity, requires a stronger system of stiffeners than that needed by a fixed-end arch, and the quantity of concrete in the stiffeners for the former must, necessarily, be greater than in those for the latter; therefore the statement advanced by the authors, that the quantity of concrete was the same in each case, cannot be accepted. Mr. Janni.

In conclusion, it is to be noted that the statement concerning the complication of design for a fixed-end arch and the ease with which such an arch can be upset by a slight movement of one of its supports, is not altogether justified. This complication of design, so much complained of, is justified only if the designer expects to calculate the arch as simply as he can pick out, from the "Carnegie Handbook," the I-beams for a floor.

Concerning the latter remark (which was correct several years ago) it can be said that, by the theory of "virtual work" or, more elegantly and speedily, by the method of the "ellipse of elasticity", the designer can easily take care of such dreaded displacement of support, and even of a yielding of the soil on which the footings rest.

There is no doubt that the design for an arch is one of the most delicate problems of engineering; but, after all, it may be done without any great trouble if the designer is sufficiently familiar with his work.

The theories used are not monopolized by a few persons, but are quite accessible to any one of training and application. Fortunately for the designer, those theories cannot be reduced to "rule-of-thumb", for several reasons. If an engineer, satisfied with what he was taught at school, does not keep in touch with the daily progress of science, he runs the risk, nowadays, of being behind the times. If, for instance, in designing an arch, he still assumes first that the arch is entirely loaded and then, that it is half loaded and half unloaded—still believing that, in this way, he ascertains the maximum stresses in that arch—he is flatly wrong; those assumptions were made several years ago, because there was then no means of ascertaining, conveniently, the most prejudicial hypothesis of loading; at present, however, that method of computing stresses is antiquated as well as inadequate.

PHILIP AYLETT, ASSOC. M. AM. SOC. C. E. (by letter).—In America, the ribbed arch, especially the three-hinged type, has not received that recognition of its merits which it deserves. Its economy and advantages are better known and more highly appreciated in Europe, where it has been used extensively under almost all conditions of site and traffic, and in great variety of form and design. Mr. Aylett.

Comparatively few concrete bridges of the rib type proper (hinged or fixed) have been built, as yet, in America, and these only within

Mr. Aylett. the past decade. The literature on the subject, therefore, is comparatively scant.

The authors of this paper deserve the thanks of all interested in the use and development of this type in America, where its future is so promising and its field so extensive.

The use of three-hinged arches on compressible material is fully justified by ample experience and precedents. The foundations of abutments and piers in such cases, however, demand more careful investigation, study, and design. A fixed or a two-hinged arch may also often be built with entire safety on compressible material, provided the foundations are properly designed and built, including the use of batter piles and other methods of taking up thrust. This also is justified by numerous structures under such conditions now extant, both in Europe and America.

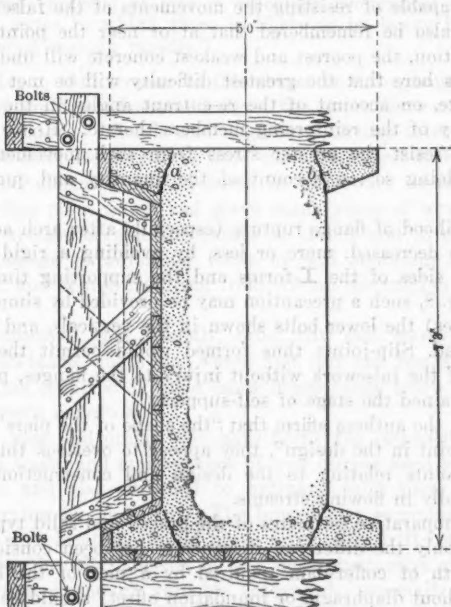
The seeming economy of the rib of I-section, as compared with the rectangular, will not show so vividly in practice as on paper. This saving in concrete in the I-section will be largely, if not entirely, offset by the greater expense caused by the additional material and labor involved in making and placing the I-forms and depositing the concrete therein. Forms for such sections also necessitate the cutting up of the lumber into many short lengths, thus making much of the material unfit for other use. For instance, Fig. 8 shows an I-section form designed for the purpose of economizing in material and in the labor of making, placing, and dismantling it. This form is also capable of repeated use, as it is built in sections with this in view. Yet the additional material and labor involved, in comparison with forms of rectangular section, is apparent at first glance.

In addition, the I-section rib invites and makes possible injury and defects to the permanent structure from which the rectangular section is exempt. No one can foresee or forestall settlements in falsework or centering from timber shrinkage, "taking up", "biting", columnar shortening, foundation movements, expansion, contraction, etc., etc. Falsework or centering moves upward as well as downward on account of the unsymmetrical placing of the load, or in cases where the falsework becomes wet by rain or flood after being thoroughly dried out. A rectangular arch rib is capable of sustaining more settlement or upward movement of the falsework without injury than is possible with an I-section, because of the projecting flanges of the latter. Settlements or movements of the falsework prior to the removal of the I-forms seriously endanger these concrete flanges, and will probably cause rupture at or near their junction with the body or web of the section, as at *a, b, c,* and *d,* of Fig. 8.

From a number of cases, it has been observed that the maximum movements of falsework (both up and down) occur during or imme-

Mr. Aylett.

diately after the construction of the arch ribs (except in cases of accidents, etc.); because this is the period of the initial adaptation or accommodation of the falsework to its superimposed load. During this period, therefore, the I-forms are always found in position and cannot be dispensed with. The danger of flange rupture is most imminent during the initial stages of arch action; that is, when arch action begins to assert itself, the concrete being comparatively green.



Note:
Forms Built in 6 to 10-Ft. Longitudinal Sections
Each Section Detached by Removal of Bolts in Verticals

Fig. 8.

Flange rupture may occur, however, after the rib has passed into the self-supporting stage, or even before arch action asserts itself at all. For instance, if a downward movement of the falsework occurs just as arch action begins to take place, the rib offers some resistance to the movement, though it may be incapable of entire self-support. The result is rupture in the bottom flanges and cracks opening upward, as at *d*, Fig. 8.

Mr. Aylett. If an upward movement of the falsework occurs (on account of swelling, distortion, or accumulation of drift and débris against the forms), flange rupture takes place in the opposite direction, the cracks opening downward, and both top and bottom flanges may be affected, as at *a*, *b*, and *c*, Fig. 8. Flange rupture prior to arch action is most likely to occur in connection with the use of heavy reinforcing members, such as I-beams, lattice girders, etc., as these, by their own arch action, are capable of resisting the movements of the falsework.

It must also be remembered that at or near the points, *c* and *d*, in the I-section, the poorest and weakest concrete will undoubtedly be found. It is here that the greatest difficulty will be met in securing good concrete, on account of the re-entrant angles in the forms, and the proximity of the reinforcing members thereto. Hence the flanges which must resist the greater stress from such movements are less capable of doing so, on account of the quantity and quality of the material.

The likelihood of flange rupture (especially after arch action in the rib) may be decreased, more or less, by avoiding a rigid connection between the sides of the I-forms and the supporting timbers below. Thus, in Fig. 8, such a precaution may be provided by simply omitting (on both sides) the lower bolts shown in the verticals, and using stop-blocks instead. Slip-joints thus formed would permit the downward movement of the falsework without injury to the flanges, provided the arch had attained the stage of self-support.

Although the authors affirm that "the shape of the piers" is a "most important point in the design", they appear to overlook this and other important points relating to the design and construction of bridge piers, especially in flowing streams.

In the comparative estimates of the braced and solid types of piers, apparently, only the difference in concrete has been considered. The greater length of coffer-dam required by a pier of the braced type (with or without diaphragm or foundation offset) should be considered. In constructing coffer-dams in flowing streams, the important thing is usually time, for more risk is attached to coffer-dam building in flowing streams than in any other operation connected with ordinary bridge building, especially where there is "ice or logs of wood moving rapidly".

The many-sided dam of the braced type pier requires much maneuvering of the pile-driver in order to effect the frequent changes of direction. This involves change of anchorage, backing, going forward, etc., etc., all by men who are not sailors, and while breasting a current, and with risk of disaster by flood.

The solid rectangular pier requires less coffer-dam, less maneuvering of the pile-driver, less exposure to flood at the most critical time, and, consequently, much less time and expense. These are among the im-

portant points which should be considered in pier design and construction, and cannot be overlooked in any estimates. Mr. Aylett.

There are, however, other features of the authors' braced pier which appear so serious as to preclude entirely this type from consideration in streams of the character mentioned.

The authors state:

"This type [braced] of pier is especially economical for a bridge in running water in which there is likely to be heavy blocks of ice or logs of wood moving rapidly."

Even prior to 1913 streams of this character throughout the country indicated, by ample evidence and signs, the imprudence of obstructing their flow. Railway officials and engineers, having interest in many streams over extended territory, were among the first to be impressed. Frequent and alarming flood records in numerous streams were observed. Bridge piers which had given many years of service, without trouble or expense, became the causes of claims and litigation on account of damage to adjoining lands by soil stripping and deposits of mud, silt, and débris, resulting from stream obstruction and current deflection.

It was observed that, usually, mud, silt, etc., were deposited in greatest abundance where the water first left the banks of running streams. This occurred in most cases immediately below bridge piers or other current deflectors.

Railway men and others who have borne the responsibility (night and day) of traffic and maintenance of way during flood periods, know the expense and risk attached to ordinary solid piers in running streams carrying ice and drift. The braced pier recommended by the authors for such locations would prove a veritable drift-trap and, viewing the matter broadly, appears to be a most obstructive and expensive type. Cut-waters, though valuable safeguards, especially against ice, do not prevent the lodgment of all logs and drift, even when solid piers of comparatively less widths are used.

The authors' braced type of pier is exposed, not only to the accumulation of drift, etc., on its nose or up-stream end, as in solid piers, but will also catch and hold rigidly logs and drift in the space between the legs on both sides (Fig. 9). Drift thus trapped and held would not float and rise with the flood as it does with solid piers; and, as it would be quickly submerged when caught, it would be almost impossible for an ordinary section gang, even with machinery, to dislodge it.

The buoyancy and enormous leverage of a mass of logs and drift, thus trapped, would exert a simultaneous lifting and wrenching action on the pier, increasing with the pressure of the rising flood on the growing mass held firmly before it.

Mr. Aylett. Drift which collects at the noses of solid piers can always be removed by ice-hooks or pike-poles and floated away. Masses of drift cause deep scour around piers, and this would probably extend below the diaphragm, if its depth were only "down to where they [the pier-legs] enter the ground." If this should occur, heavy drift from both sides might find its way under the diaphragm as well as the braces. It is difficult to reconcile the obstructive braced pier recommended by the authors with the nation-wide conservation movement of to-day, especially in the face of the experience of the West and Middle West in 1913, with its lessons so clearly, impressively, and profoundly taught.

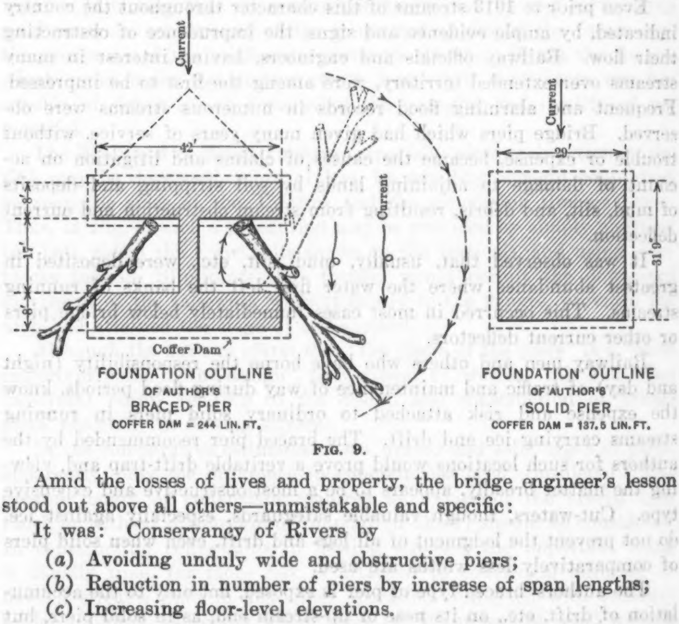


FIG. 9.

Amid the losses of lives and property, the bridge engineer's lesson stood out above all others—unmistakable and specific:

It was: Conservancy of Rivers by

(*a*) Avoiding unduly wide and obstructive piers;

(*b*) Reduction in number of piers by increase of span lengths;

(*c*) Increasing floor-level elevations.

These would facilitate the discharge and consequently help to lower the flood level. By so doing, other lives and property may be saved, and the sacrifices in the West and Middle West will not have been in vain.

Mr. Mensch. L. J. MENSCH, M. AM. SOC. C. E. (by letter).—The statement of the authors that three-hinged arches contain only about half as much masonry as properly designed fixed arches is only true for bridges of very small rise, and the writer would be interested to see the calculations for the bridges shown in Fig. 3, as his own tables do not

show such a difference. The fact is that the thrust in both types is practically the same. The bending moment caused by a concentrated load in a three-hinged arch is greatest when the load is 0.211 l from the abutment, and its value is about $P \times \frac{l}{10}$; in a fixed arch a concentrated load produces the greatest bending moment when placed 0.3 l from the abutment, and its value is about $P \times \frac{l}{16}$. Mr. Mensch.

It is customary to calculate a bridge for a uniform load, w, placed at its half span. The greatest bending produced in a three-hinged arch occurs at the quarter span, and amounts to $\frac{w \times l^2}{64}$; in a fixed arch it occurs at the point 0.3 l from the abutment, and amounts to $\frac{w\,l^2}{120}$; at the same time the moment at the abutment is $\frac{w\,l^2}{64}$.

There is nothing to justify the statement that there is a considerable saving in materials in a three-hinged arch over a fixed arch, unless the temperature stresses and the stresses due to the shortening of the arch and the shrinkage of the concrete play an important rôle, which is only the case in arches of comparatively small rise and large depth. Professor Howe, in his treatise on arches, showed that the thrust from a change of temperature in a parabolic arch of constant $\frac{d\,s}{I}$ may be found by the formula, $\frac{45}{4}\,\frac{E\,I\,c\,t}{f^2}$, when E = the modulus of elasticity, I = the moment of inertia of the crown section, c = coefficient of expansion, t = change of temperature, in degrees Fahrenheit, and f = rise of arch; and that its point of application should be assumed at $\frac{1}{3}\,f$ below the crown. The writer finds that in a parabolic arch, as usually designed, the thickness of the arch increasing at the abutment to about $1\frac{1}{2}$ to 2 times the crown thickness, the thrust may be found by the formula, $24\,\frac{E\,I\,c\,t}{f^2}$, and its point of application may be assumed to be $\frac{7}{30}\,f$ below the crown. Let $E = 2\,000\,000$, $t = 50°$, $c = 0.0000055$, or $E\,c\,t = 550$.

From a change of temperature, the bending moment is found to be,

at the crown, $$\frac{24\,I}{f^2} \times 550 \times \frac{7}{30}\,f = 3\,080\,\frac{I}{f};$$

at the abutment, $$\frac{24\,I}{f^2} \times 550 \times \frac{23}{30}\,f = 10\,120\,\frac{I}{f}.$$

For a width of 1 ft. of the arch ring, $I = \frac{12\,d^3}{12}$, when d = the thick-

Mr. Mensch.

ness at the crown; the moment at the crown $= 3\,080\ \frac{d^3}{f}$, and the moment at the abutment $= 10\,120\ \frac{d^3}{f}$.

If we consider that the moment of resistance of the crown section for a width of 12 in. (neglecting the reinforcement) $= \frac{12 \times d^2}{6} = 2\,d^2$, and that the moment of resistance at the abutment, when the thickness is twice the crown section $= \frac{12 \times 4d^2}{6} = 8d^2$, we can obtain for the stresses in the extreme fibers caused by the change of temperature, by dividing the moments by the section modulus, the simple expressions, $1\,540\ \frac{d}{f}$ for the crown section, and $1\,265\ \frac{d}{f}$ at the abutment, whatever the span of the arch.

The writer will endeavor to compare the two bridges shown in Fig. 3, as far as the few measurements given will allow. He will assume that the thrust per linear foot may be found by the formula, $\frac{850 \times 128.5^2}{8 \times 25} = 70\,000$ lb. The live load of 100 lb. per sq. ft. distributed over a width of 29 ft. will amount to $\frac{100 \times 29}{17} = 170$ lb. if distributed over the two arch rings 17 ft. wide; and the bending moment in a three-hinged arch at the quarter span

$$= \frac{170 \times 128.5^2}{64} = 44\,000 \text{ ft-lb. per lin. ft.}$$

The crown thickness of the arch is 22 in., and, assuming that the thickness at the quarter point is 33 in., the stresses at the quarter point may be found as follows:

The compressive stress $= \frac{70\,000}{33 \times 12} = 177$ lb. per sq. in.

The stresses in the extreme fibers from the bending moment

$$= \frac{44\,000 \times 12}{12\ \frac{33 \times 33}{6}} = 242 \text{ lb.}$$

or a maximum compressive stress of $177 + 242 = 419$ lb. and a maximum tension of $242 - 177 = 65$ lb.

The average thickness of the arch is $22 + \left(\frac{2}{3} \times 11\right) = 29.33$ in.

In a fixed arch it will be necessary to assume a greater thickness of the arch at the crown, on account of the temperature stresses; therefore, the thickness at the crown will be assumed to be 28 in. and that

Mr. Mensch.

at the abutment, 56 in. The maximum bending moment caused by a uniform load, w, per square foot at the crown is about $\frac{w \times l^2}{320}$, and the compressive stress from the thrust $= \frac{70\ 000}{12 \times 28} = 208$ lb. per sq. in.; the stresses in the extreme fibers, from the uniform load, $= \frac{170 \times 128.5^2}{320}$, divided by $\frac{12 \times 28^2}{6} = 56$ lb. per sq. in.

As shown before, the temperature stress in the extreme fibers $= 1\ 540 \frac{d}{f} = 144$ lb. per sq. in., or a maximum compressive stress of $208 + 56 + 144 = 408$ lb. and a minimum compressive stress of $208 - 200 = 8$ lb. per sq. in. At the abutment, the thrust is $70\ 000 \times 1.28 = 89\ 500$ lb. and the compressive stress $= \frac{89\ 500}{12 \times 56} = 133$ lb. The maximum bending moment from a uniform load

$$= \frac{170 \times 128.5^2}{64} = 44\ 000 \text{ ft-lb.}$$

The section modulus at the abutment $= \frac{12 \times 56^2}{6} = 6\ 280$ in.^{3}, and the stresses in the extreme fibers $= \frac{44\ 000 \times 12}{6\ 280} = 84$ lb.

The temperature stresses $= 1\ 265 \frac{d}{f} = 118$ lb., or the maximum compressive stress $= 133 + 84 + 118 = 335$ lb. per sq. in., and the maximum tensile stress $= 202 - 133 = 69$ lb. per sq. in. The average thickness of the arch $= 28 + \left(\frac{1}{3} \times 28\right) = 37.33$ in.

The stresses from the shortening of the arches will modify the results only very slightly in this case. Although both bridges have about the same stresses, the average quantity of concrete is only 27% greater in the fixed than in the three-hinged arch. Or, assuming that 200 cu. yd. for the three-hinged arch is correct, the saving amounts to only 54 cu. yd., or $675, which is more than counterbalanced by the cost of steel hinges.

The authors state that the slightest movement of the abutments will develop cracks in the arches. This is not the case. A temperature drop of 50° is equivalent to a movement of both abutments of $\frac{1}{3\ 640}$ of the span, or, in this case, 0.42 in., and it is a poorly designed abutment in which this movement will be seen. Such a movement would increase the stresses at the crown to $408 + 144 = 552$ lb. in compression and $144 - 8 = 136$ lb. in tension, and at the abutment to 335 +

Mr. Mensch. 118 = 453 lb. in compression and 69 + 118 = 187 lb. in tension. It is known that ordinary slabs do not crack under stresses less than 300 lb. per sq. in.; hence the factor of safety against the first crack is still ample.

It is true, however, that the temperature stresses and those due to the shortening of the arch would be three or four times as great in the same arch with a rise of only one-tenth of the span, and the advantage of the three-hinged arch in such a case is unquestioned.

In a three-hinged arch, great stresses may be caused by the unequal settlement of the staging, and it has often happened that the hinges have been thrown out of line and out of center, and have had to be dug out and replaced. The failure of a large bridge was due to this cause. This is the main reason that fixed arches are preferred by experienced engineers to the three-hinged type.

It must also be mentioned that three-hinged arches settle considerably more than fixed arches after the centering is struck, and also cause more vibration under moving loads.

In three-hinged arches, the use of deep ribs is a decided saving, which is not the case in all fixed arches. The writer has advocated* the use of I-sections for spans of more than 300 ft., and for spans of from 200 to 300 ft. he advocates T-sections.

The rule given by the authors for finding the center line for a three-hinged arch can be simplified by assuming the entire arch to be loaded by one-half of the uniform load per square foot. This, according to the elastic theory, gives the most favorable line of pressure.

Mr. Buel. A. W. Buel, M. Am. Soc. C. E. (by letter).—Mr. Gregory, Mr. Janni, and others have brought out most of the points involved, but there remains one of vital importance as affecting the comparison of the hinged and fixed-arch rib as made by the authors. Although they have used the proper form for their hinged ring, their fixed ring is neither correct nor economical, and, therefore, is not a fair comparison. Being segmental, it is subject to great moments at the springing line, as the ring does not conform to any pressure line for any practical conditions.

The only economic justifications for the three-hinged ring are difficult foundation conditions and a rise of less than one-sixth of the span with a possible yielding of the abutments.

The authors exaggerate the difficulty of computing the fixed arch, for, by systematizing and tabulating the work, it is quite possible to make the computations in 2 days or less. Moreover, it does not seem to be good engineering practice, nor creditable to the industry of the Profession, to advocate a design because it may save a few hours or even a few days of work for the designer. This is aggravated when there is room for the suspicion that any such saving in the designer's

* "The Reinforced Concrete Pocket Book."

time and energy is largely due to his unfamiliarity with fixed-arch computations. Mr. Buel.

The advantages of the ribbed ring have been demonstrated and advocated* by the writer in designs worked out in 1899 and 1901.

W. D. Maxwell, Assoc. M. Am. Soc. C. E. (by letter).—The question of temperature changes in arches has been mentioned by several who have discussed this paper. Mr. Maxwell.

When the Walnut Street Concrete Bridge, of which the writer was one of the designers, was built in Des Moines, Iowa, in 1911, nine electrical resistance thermometers were embedded at various points in one of the arches. This arch has a clear span of 68 ft., a crown thickness of 16 in., and a solid spandrel fill. The greatest range in temperature was at the crown, where an average of two thermometers showed a temperature of 86° Fahr. about 16 hours after pouring, 9° below zero as the low point during the following winter, and 86° in the summer of 1912, one year after the bridge was built. Other thermometers placed in thicker portions of the arch showed somewhat less susceptibility to atmospheric changes. The average of two instruments embedded about 2 ft. in heavy concrete near the pier and abutment showed 98° Fahr. about 36 hours after pouring, 20° the next winter, and 85° the following summer. The average of all the thermometers for the first 6 months, gave a range of temperature in the concrete of 87.6 degrees. The upper limit of this range was the extreme produced by the heating of the setting concrete. The average of all the thermometers for the second 6 months was 79.2 degrees.

The extremes of atmospheric temperature in the summer of 1911 and the following winter were very great for this locality, the total range being 135 degrees. However, ranges of considerably more than 100° may be expected every year.

Elevations were taken on all six arches of the bridge in September, 1911, when the average of all the thermometers was 75°, and again in January, 1912, when the average was 11 degrees. The difference corresponded closely to that computed for a change of 64° in the temperature of the concrete.

In the design of the bridge, allowance was made for a 40° rise, and a 40° fall. These amounts were considered excessive by some engineers, but the actual observations show that they were not only not too small, but that the fall was more than 40°, the concrete having been poured at a general average of about 70 degrees.

Considering these temperature ranges, it is apparent that concrete bridges built in these rigorous climates, especially the hingeless arches, must be very carefully reinforced against temperature stresses, and it is also evident that the warmer climates and those having nearly uni-

* "Reinforced Concrete," First Edition, 1904.

Mr. Maxwell. form yearly temperatures possess a real advantage with this type of construction.

Mr. W. M. Smith, Sr. WALTER M. SMITH, SR., M. AM. SOC. C. E. (by letter).—Mr. Gregory states that the decision to adopt a three-hinged arch for the Traver Hollow Bridge was taken because the foundations for the abutments and piers would be on compressible material. He also states that the preliminary estimates indicated that the three-hinged arch would be somewhat more expensive than the fixed-arch type. He is correct in the first statement, but is mistaken in the second. Only a rough estimate was made for a fixed arch at this site, making certain assumptions as to the depth to rock. Careful designs and estimates were then made for a three-hinged arch, to compare with the other. The writer had charge of both estimates, and made the design and estimate for the three-hinged arch. He has copies of these estimates before him as he writes. If the same unit prices are taken for the three-hinged arch as for the fixed arch, the saving would be about 30% for the former. Therefore the average increase in unit price for the three-hinged arch would have to be 43% in order that it might cost as much as the fixed arch for this site. When these estimates were obtained, as there was no information at hand as to the depth to rock, it was decided to build the three-hinged arch, as it was certain that the material would carry the load of an arch of this type by compressing slightly, and would not injure the arch.

Figs. 10, 11, and 12 show the details of the hinges and the method of connecting them to the steel ribs of the arch. It will be seen that the steel forms a continuous structure between the abutment hinges, with an additional hinge at the crown.

When the design of the Rye Outlet Bridge was under consideration, the writer also investigated a three-hinged arch for this site, at Mr. Gregory's request. As the height of the roadway was fixed, and also the water line, the design was limited to short arches, unless it was admissible to construct them with a ratio of rise to span of more than six, on very high piers. It was thought inadvisable to do this. With short arches the three-hinged type showed such a slight saving over the fixed type that the latter was adopted, as the piers were to be founded on bed-rock.

Mr. Gregory is wrong in supposing that the pier shown in the paper is one of those in the Rye Outlet Bridge. In reference to this pier, the paper states that, "The first is a braced pier somewhat similar to those in the Rye Outlet Bridge." The thrusts, shown as acting at the top of this pier, are assumed, and, so far as the writer knows, they may not be anywhere near those of the piers in the Rye Outlet Bridge. They were taken arbitrarily, and the piers were designed to suit the thrusts; therefore the writer fails to see how the investigation mentioned by

Mr. W. M. Smith, Sr.

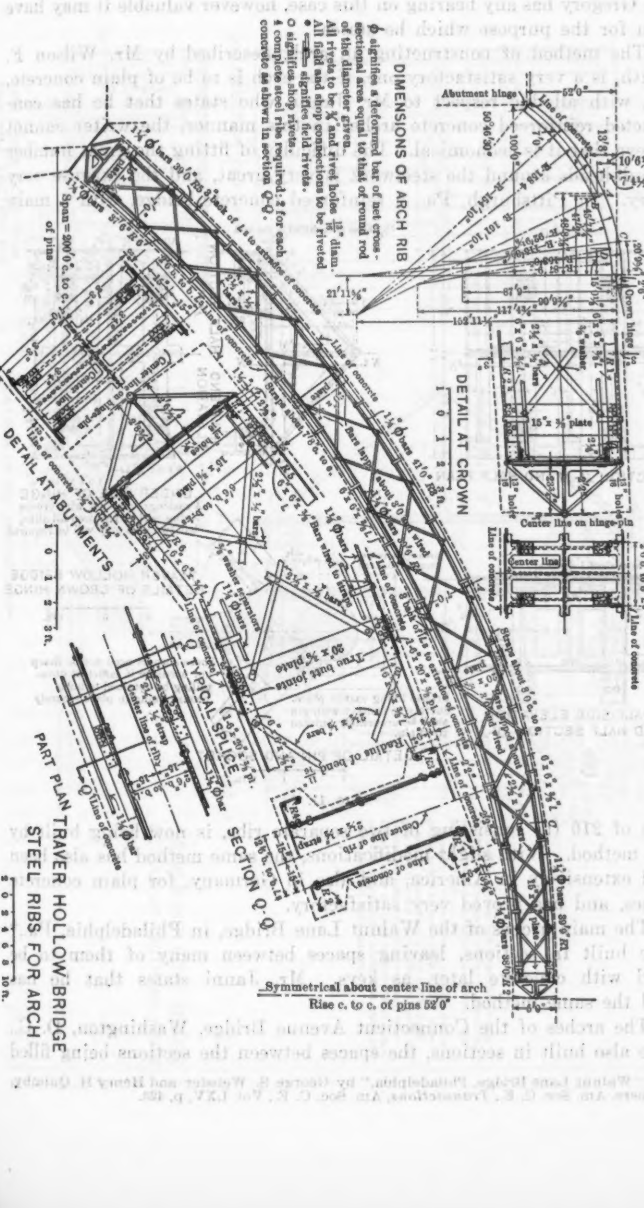

Fig. 10.

Mr. W. M. Smith, Sr.

Mr. Gregory has any bearing on this case, however valuable it may have been for the purpose which he states.

The method of constructing an arch, described by Mr. Wilson F. Smith, is a very satisfactory one, if the arch is to be of plain concrete, but, with all due respect to Mr. Janni, who states that he has constructed reinforced concrete arches in this manner, the writer cannot believe that it is economical. The difficulty of fitting the great number of bulkheads around the steelwork is very great, and the expense very heavy. In Pittsburgh, Pa., a reinforced concrete bridge, with a main

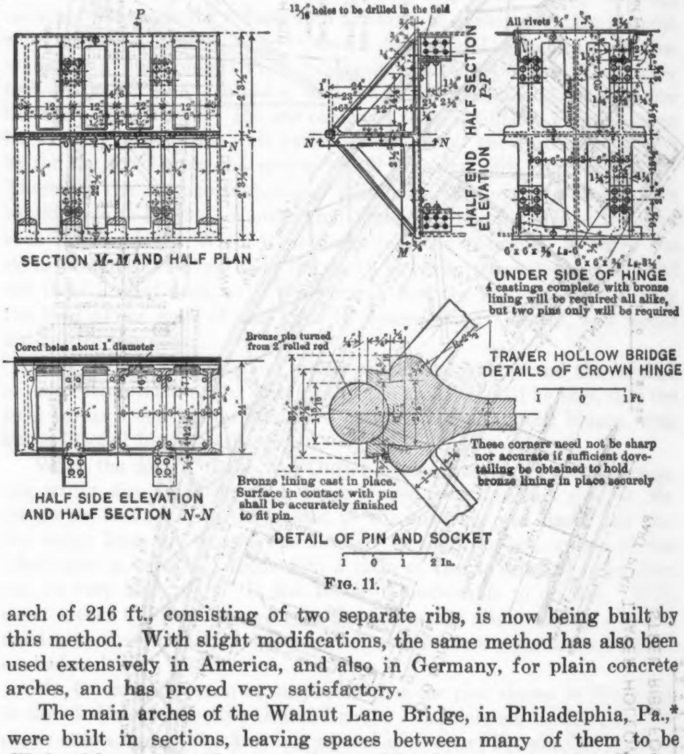

Fig. 11.

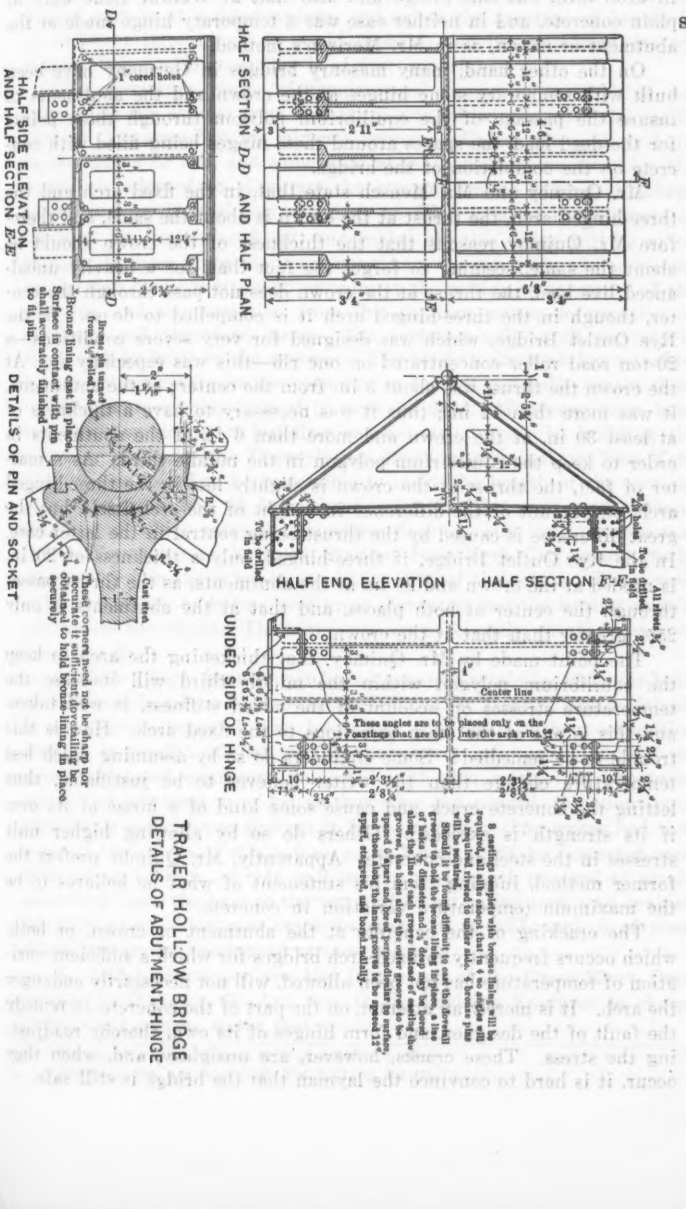
arch of 216 ft., consisting of two separate ribs, is now being built by this method. With slight modifications, the same method has also been used extensively in America, and also in Germany, for plain concrete arches, and has proved very satisfactory.

The main arches of the Walnut Lane Bridge, in Philadelphia, Pa.,* were built in sections, leaving spaces between many of them to be filled with concrete later, as keys. Mr. Janni states that he has used the same method.

The arches of the Connecticut Avenue Bridge, Washington, D. C., were also built in sections, the spaces between the sections being filled

* "Walnut Lane Bridge, Philadelphia," by George S. Webster and Henry H. Quimby, Members. Am. Soc. C. E., *Transactions*, Am. Soc. C. E., Vol. LXV, p. 423.

Mr. W. M. Smith, Sr.



TRAVER HOLLOW BRIDGE
DETAILS OF ABUTMENT HINGE

FIG. 12.

Mr. W. M. Smith, Sr. in afterward, but this bridge and also that at Walnut Lane were of plain concrete, and in neither case was a temporary hinge made at the abutment or crown, as in Mr. Morison's method.

On the other hand, many masonry bridges in Germany have been built with temporary stone hinges at the crown and the abutments to insure the passage of the equilibrium polygon through these points for the dead load, the spaces around these hinges being filled with concrete on the completion of the bridge.

Mr. Quimby and Mr. Mensch state that, in the fixed arch and the three-hinged arch, the thrust at the crown is about the same, and therefore Mr. Quimby reasons that the thickness of the crown should be about the same, seeming to forget the fact that, for a heavily unbalanced live load, the thrust at the crown does not pass through the center, though in the three-hinged arch it is compelled to do so. In the Rye Outlet Bridge, which was designed for very severe conditions—a 20-ton road roller concentrated on one rib—this was especially so. At the crown the thrust was about 5 in. from the center; at the abutments, it was more than 12 in.; thus it was necessary to have a thickness of at least 30 in. at the crown and more than 6 ft. at the abutments in order to keep the equilibrium polygon in the middle third. As a matter of fact, the thrust at the crown is slightly less in the three-hinged arch, on account of the difference in weight of the arch itself, but the great difference is caused by the thrust being central in the latter case. In the Rye Outlet Bridge, if three-hinged, only a thickness of 20 in. is needed at the crown and 25 in. at the abutments, as the thrust passes through the center at both places, and that at the abutments is only 25% greater than that at the crown.

The point made by Mr. Quimby, that thickening the arch to keep the equilibrium polygon within the middle third will increase the temperature stresses on account of the added stiffness, is well taken, and this is one of the main objections to the fixed arch. How is this trouble to be remedied? Some engineers do so by assuming much less temperature change than the writer believes to be justifiable, thus letting the concrete crack and cause some kind of a hinge of its own if its strength is exceeded. Others do so by allowing higher unit stresses in the steel and concrete. Apparently, Mr. Quimby prefers the former method, judging from his statement of what he believes to be the maximum temperature variation in concrete.

The cracking of the concrete at the abutment or crown, or both, which occurs frequently in fixed-arch bridges for which a sufficient variation of temperature has not been allowed, will not necessarily endanger the arch. It is merely an attempt, on the part of the concrete, to remedy the fault of the designer, and form hinges of its own, thereby readjusting the stress. These cracks, however, are unsightly, and, when they occur, it is hard to convince the layman that the bridge is still safe.

The writer has stated that, with regard to appearance, the three-hinged arch is at a disadvantage, and, when the question of beauty is of sufficient importance, it would probably not be considered, its advantage being where economy is of first importance. Mr. W. M. Smith, Sr.

The maximum range of temperature change in an arch is not necessarily the change from midsummer to midwinter, with the condition of "no stress" lying midway between. Unless the arch is built in the spring or fall, and some method (such as that described by Mr. Janni) is adopted to eliminate the stresses due to setting shrinkage by leaving in the arch key spaces to be filled in after the concrete of the arch has been placed, set, and cooled off, this range will be much higher. If these precautions are not taken, the condition of "no stress" in the arch is the position it occupies at the setting temperature of the concrete, and any variation from this position causes deformation of the arch, and, therefore, stress. The variation will be all one way if the bridge be built in the summer. The steel in the arch has no effect in preventing cracks in the concrete, in fact, it generally causes them to occur more quickly than if it were not used. Many engineers have had this experience in building various structures. In building the retaining walls for the Pennsylvania Railroad terminal, in New York City, it was found to be impossible to make the length of the sections of wall greater than 25 ft. without cracks.* The reinforced concrete floor beams, which carry the concourse floor of vault light construction in the Pennsylvania Railroad Station, New York City, show cracks where they join the columns at almost 50% of the points. These were built as continuous beams over great distances, and the setting shrinkage caused the cracks. The beams are not necessarily unsafe because of these cracks.

In 1908 a high, heavily reinforced concrete retaining wall was built along the railroad yard on the water-front at St. George, Staten Island. It is several thousand feet long, and was built without expansion joints. In the fall of that year the writer was informed, by one of the most prominent engineers connected with this work, that expansion joints had not been provided as they were not needed, the quantity of steel being sufficient to prevent it from cracking. The writer had seen some of the effects of this before, so in March, 1909, he inspected carefully about 1 000 ft. of this wall, and in that length counted 45 cracks extending from the base to the top, and 17 extending part way, making an average of about one crack in every 16 ft. Through 8 of these cracks water was issuing at various heights.

A similar experience was had in the top of the Cross River Dam. George G. Honness, M. Am. Soc. C. E., Division Engineer in charge of its construction, states that:†

* *Transactions*, Am. Soc. C. E., Vol. LXVIII. p. 334.

† *Transactions*, Am. Soc. C. E., Vol. LXI. pp. 411-418.

Mr. W. M. Smith, Sr.

"It was not expected that the use of these rods would entirely eliminate the temperature cracks, but it was hoped that it would prevent their concentration in a few large cracks.

* * * * * * *

"The reinforcement * * *—as to quantity and method of placing—was not effective in preventing the concentration of the cracks."

The following is given as an example of how greatly concrete shrinks in setting. On some work with which the writer was connected, some years ago, it became necessary to cut out some concrete in a ceiling consisting of a very deep and heavy concrete slab with reinforcing bars embedded about 2 or 3 in. from the lower surface. The concrete was cut from around a few of these bars for a distance of about 2 ft. All the bars, when released, sprang out of line, thus showing that the shrinkage of the concrete, in that short distance, was sufficient to shorten the steel bars by compressing them. Theoretically, these bars were carrying a tension of 16 000 lb. per sq. in. In reality, they were in compression, and the concrete was not only carrying all the load, but was also compressing the steel.

Many experiments have been made in order to determine the rise in temperature in cement mortar, neat and of various compositions, and of concrete during setting. In some tests by the Universal Portland Cement Company on neat cement cubes, the average temperature rise was from 80° to a little more than 130° Fahr., in from 6 to 8 hours after placing. In the case of concrete, the initial temperature, 70° Fahr., was increased to 80° in 8 hours, 100° in 25 hours, and 105° in 45 hours. Tests in the laboratory of Lehigh University have shown that the temperature of an 8-in. cube of 1 : 3 Portland cement mortar rose from an initial temperature of 70° to 160° Fahr. in 18 hours. At the Watertown Arsenal, a few years ago, tests of 29 cubes of neat cement, representing 27 brands of cement, were made. The initial temperature was 77°, and the average maximum 185° Fahr., showing a rise of 108° in an average of 13 hours. The thermophones embedded in the cyclopean masonry of the Boonton Dam indicated a rise from 20 to 25° Fahr., although only about two-thirds of the mass consisted of concrete. In the locks of the Panama Canal the rise was also about the same.

Table 1 shows the setting temperature in some concrete canal walls at Madison, Me., built for the Hollingsworth and Whitney Company. As the concrete was placed in the winter, it was first heated to 70° Fahr. The average atmospheric temperature was 11° and that of the concrete 108°, showing a rise of 38° after being placed, in spite of the exceedingly low outside temperature.

As an example of the low temperature which may be reached in bridge arches in the Northern States, Table 2, showing the results of tests on the Squaw Creek Bridge, at Ames, Iowa, is interesting.

center of the pier, Nos. 6 and 7 in the center of the arch half way between the springing line and the crown, and Nos. 8 and 9 in the center of the arch at the crown. The arch is not exposed on its upper side, as there is an earth fill above it. Coils Nos. 6 and 7 are about 9½ in. from the surface, and Nos. 8 and 9 about 8 in., consequently the heat

generated by the setting would be dissipated much more rapidly at Nos. 6, 7, 8, and 9, than at the others. Conversely, these four reach temperatures much lower in winter and somewhat higher in summer than the others. As the upper surface of the arch is protected by an earth fill, the range there is probably not as great as it would be if the arch had open spandrels, therefore the variations are on the conservative side. Mr. W. M. Smith, Sr.

It is evident, in this case, that the concrete set and the arch took its shape at a temperature of more than 90 degrees. Any deviation from this temperature, then, would cause stress in the arch. As all the thermometers in the arch itself reached zero, or went below zero, during the following winter, the arch was subjected to a stress due to a variation of more than 90° from the normal. The arch was designed for a variation of 40° each way from the normal, therefore it was subjected to 2¼ times as great a range as that for which it was designed. What is likely to happen in such a case? Probably the arch will crack, either at or near the abutments, or at the crown, or at both. As the arch at the abutments or piers is much deeper, and therefore much more rigid, than at the crown, the cracks are more likely to appear there. When the concrete cracks, the stress is readjusted, and the arch has formed somewhat of a hinge for itself. As stated previously, the arch is not necessarily endangered by these cracks, as they cause a readjustment of the stress, but they are unsightly, and it is difficult to convince a layman that the arch is perfectly safe.

In his report Mr. Maxwell states that at that time there were no cracks in the Walnut Street Bridge, but in the Squaw Creek Bridge there are unsightly cracks at the exact point of computed maximum stress at three of the four corners of the bridge. He also states that in the Locust Street Bridge, Des Moines, Iowa, there are cracks at the crown of each of the shore spans.

As all these arches were designed for a variation of 40° each way from the normal, Mr. Maxwell concludes that for northern latitudes a variation of this much should be allowed, and that:

"Particular circumstances may demand that a greater variation be used for drop in temperature to prevent the appearance of cracks."

This conclusion was reached by the writer some years ago. If, in the face of these facts, an engineer is willing to design a bridge for a variation of only 20° each way from normal, as Mr. Quimby seems to propose, and then lets the bridge crack and form its own hinges, the writer freely admits that it will be a cheaper bridge than a three-hinged arch designed for reasonable stresses.

It is admitted that, if a stone hinge be used in an arch, the friction of the hinges should be taken into consideration in computing the stress due to change of temperature, but with a metal hinge, such as

Mr. W. M. Smith, Sr. that in the Traver Hollow Bridge, the amount would be so small as to be negligible. The writer would like to call Mr. Janni's attention to the details of these hinges and the arch rib, Figs. 10, 11, and 12. He will see that the span of the arch is 200 ft., and that the diameter of the pin at the abutment hinge is about 3 in., and at the crown 2 in.; therefore the maximum deviation of his lines, P_1 and P_4, would be 10 in. in 110 ft., which is certainly not very serious, to say the least. The pressure on these pins is about 12 000 lb. per sq. in. The socket for holding the pin is very heavy and rigid, so as to cause very nearly an even distribution of pressure on the pin, and a lining is cast in the socket and then finished to fit the pin accurately. The metal of the body of the hinge is cast steel having an elastic limit of 40 000 and a tensile strength of 76 000 lb. per sq. in., an elongation of 20% in 2 in., and a reduction of area of 41.5 per cent. A sample of this steel, ½ in. thick, was bent 180° around a diameter of 1½ in. without a sign of cracking either on the outside or inside of the bent portion. The socket of the casting was lined with "Monel" metal by casting it in place and then machining it to fit the pin accurately. The pin was of the same metal, finished from a rolled bar. This metal is a natural alloy of approximately the following composition: nickel 68%, copper 31%, and iron 1 per cent. The writer has a sample of this metal which tested as follows: tensile strength, 100 000 lb. and elastic limit 71 600 lb. per sq. in., elongation, 35% in 2 in.; reduction of area, 54.7 per cent. Now, with this metal as a bearing for the hinges, even if there was the concentration of pressure which Mr. Janni thinks is so serious, there would still be a factor of safety of 3 on the elastic limit of the material, and this, the writer thinks, is sufficient.

For the bending moment due to friction on the pin, the coefficient of friction of the pin and lining may be assumed at 0.20. The best authorities give this coefficient, for metal on metal, dry, as from 0.15 to 0.25; and, as this bearing is bronze on bronze, it will probably be nearer the lower limit, so that 0.20 should certainly be conservative. The total pressure on the pin is about 2 000 000 lb., therefore the bending moment of the friction at the surface of the pin, with the lever arm of 1½ in., will be $2\,000\,000 \times 0.20 \times 1.5 = 600\,000$ in-lb., which would be the moment caused by the pressure line deviating from the center line by less than 0.3 in., as the pressure decreases as the distance from the pin increases.

Mr. Janni speaks of taking care of the stress due to dead load and that due to shrinkage by neutralizing their effects, as much as possible, by the method mentioned previously, that is, by building the concrete of the arch in sections and leaving key spaces between them to be filled in after the cement has set—in not less than 10 days, he states. His reference to neutralizing the dead load stresses is supposed to mean the stresses caused by the pressure line for dead load leaving the center

Mr. W. M. Smith, Sr.

line of the arch and thus causing a bending moment, as direct compressive stresses caused by the dead load, of course, cannot be neutralized in any way. All that is necessary to accomplish this is to design the arch so that the center line is the pressure line for the dead loads on the arch. When the dead load has been obtained, it is very easy to do this. As stated previously, this is probably as good a method as can be found, for a fixed arch, to neutralize the stresses due to setting, but is, certainly, very expensive; and it does not affect the stresses due to a change from the atmospheric temperature at which the arch was cast to the extreme variation either way.

In any of the Northern States the average temperature for June, July, and August is higher than 70°, and the winter temperature goes well below zero at frequent intervals. Therefore, in any open spandrel arch built in the Northern States during these three months, the drop in temperature will probably be—as a conservative estimate—at least 60 or 65 degrees. Mr. Maxwell has shown that, in Iowa, at least, the range will be much more than that.

If all arches could be built between March 15th and May 15th, or between September 15th and November 15th, this trouble would not occur, and a method of neutralizing the stresses due to setting, similar to Mr. Janni's and allowing a range of 40° each way from the normal, would probably insure the arch against cracks.

In Mr. Aylett's Fig. 8, an arch of I-section, there would probably be some danger of the flanges breaking off, as he suggests. These flanges should be at least twice as thick as shown by Fig. 8, as it is not practicable to approach the thinness of the steel beam flange with concrete. The proportions used in the Traver Hollow Bridge are shown on Fig. 10.

The writer, however, cannot see that there is much danger of these flanges being broken off, as the load of the arch is carried to the falsework as a distributed load across its lower surface. The paneling of the sides is of light construction and is not independent of the falsework, therefore it has to move with it, and, as the movement of the falsework is caused by a corresponding movement of the arch, the whole structure must, of necessity, move together.

It may be of interest to state that the writer has a letter from the contractor who built the Traver Hollow Bridge, stating that no difficulty was experienced in its construction.

The writer will admit that, if piers are to be built in a flowing stream, in which there are quantities of tree trunks with the boughs all nicely trimmed off a short distance from the trunk, so that they can catch on anything with which they come in contact, as shown in Mr. Aylett's Fig. 9, there might be danger of a quantity of drift collecting around the piers. However, he does not believe that there is much danger of an object, after being deflected by the cut-water,

Mr. W. M. Smith, Sr. being drawn in again quickly enough to be caught by the down-stream leg of the pier. He can see no danger whatever of a tree trunk being deflected by the cut-water and then running in again with its butt between the legs of the pier, and then swinging around and hanging there. The cut-water throws the water away from the pier, and, on account of this obstruction, the water will be slightly higher as it passes, and hence the velocity will be increased. Any object deflected by the cut-water will be carried away from the pier slightly by this elevation of the water, instead of being drawn in.

In streams subject to heavy floods, where any obstruction of the channel would be serious, it is probable that wide piers would be out of the question, and undesirable, no matter what the economy would be in theory. The writer does not wish to be understood as claiming that the braced pier shown should be adopted in all cases, by any means, for he believes that the conditions at every important bridge should be investigated carefully. He thinks, however, that the braced pier is worthy of investigation when the design for a bridge is taken up.

Mr. Mensch is mistaken if he thinks that the writer claims, as a general thing, that the concrete in a three-hinged arch is about 50% less than in one that is fixed, and no statement to that effect was made in the paper. This happened to be a case where the comparison was unusually favorable to the three-hinged arch, as the proportion of rise to span is almost 1 to 6. The writer used this arch because he had designed it some years ago for the Rye Outlet Bridge, and had all the dimensions on hand, and wished to compare a three-hinged arch with it. There are five arches in the Rye Outlet Bridge, and this is the center span taken for a single-arch bridge.

It is an interesting fact that though this comparison is so favorable for the three-hinged arch for a single span, when it is applied to the Rye Outlet Bridge there is very little difference in cost, not more than about 4%, if one does not take into account the steel reinforcement. The reason for this is that the bridge piers are so high and the superstructure so massive that the total cost of the arch concrete is only 13% of the cost of the bridge, and $13 \times 0.48 = 6.25\%$ without allowing for the cost of the hinges. Taking these into consideration, the difference is reduced to about 4 per cent.

In stating the conclusions in the paper the writer did not mean to claim that every individual design would necessarily agree with these conclusions, but that they were true in the average case. He thinks that the paper has brought out a valuable discussion on a subject which, heretofore, has not been treated at length, and is glad that the matter was brought up. He has not found anything in the discussion, however, to cause him to change his conclusions, but has been further strengthened in them.

Paper No. 1295

STRESSES IN WEDGE-SHAPED REINFORCED CONCRETE BEAMS.

By William Cain, M. Am. Soc. C. E.

With Discussion by Messrs. A. C. Janni, L. J. Mensch, L. H. Nishkian, and William Cain.

In the design of reinforced concrete walls, it is often necessary to find the stresses in beams with faces inclined to each other, as in the toes, heels, face-slabs, and counterforts of such walls. In other cantilever constructions, the upper and lower faces are often inclined to each other, so that the subject is one of importance, and a practical solution is offered in this paper.

First consider the beam, Fig. 1, the upper face of which is inclined at an angle, β, to the lower face, supposed to be horizontal. This beam may be supposed to be the toe of a reinforced concrete retaining wall, and to be subjected to a soil reaction, acting vertically upward, which produces shear and also stresses due to the bending moment, in any vertical section, $N\ I$.

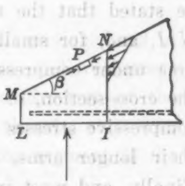

Fig. 1.

To effect a practical solution, it will be assumed that all the compressive bending stresses act parallel to the top face, $M\ N$, down to the neutral axis. This is the direction of the stress at any point of the upper surface, $M\ N$; for, consider a small rectangular parallelopiped of the concrete at P, with faces parallel and perpendicular to $M\ N$. There can be no shearing stress on $M\ N$, as no part of the beam extends above $M\ N$ to produce shear, and there is no external

force acting on $M\ N$ except the atmospheric pressure, which does not exert any friction on the face. It must follow that there can be no shear on the planes at right angles to $M\ N$, as unit shears on planes perpendicular to each other are equal.* Consequently, the compressive stress on a plane at P, at right angles to $M\ N$, is normal to it, or parallel to the face. This conclusion has been proved experimentally by Messrs. Wilson and Gore, in their exhaustive experimental work on india-rubber model dams.† They state, as one conclusion: "The maximum principal stresses near the down-stream face act on planes normal to that face," and add in a foot-note, "This agrees with Rankine's statement and with the theorem demonstrated by Mr. M. Levy." In the discussion on that paper, the same point was brought out by several speakers.

It is then plain that the compressive stress at N, Fig. 1, similarly, acts parallel to the face, $M\ N$. If this were a homogeneous beam, the tensile stress at I would similarly act parallel to the lower face. Consequently, in going from N to I, the intermediate bending stresses would gradually change their direction from $M\ N$ to $L\ I$.‡ Hence the foregoing assumption, that all the compressive stresses are parallel to $M\ N$, is to be regarded only as an approximation necessary to derive workable formulas.

In justification of its use for reinforced beams, however, it may be stated that the neutral axis is generally above the mid-point of $N\ I$, and, for small percentages of steel, much higher; so that the area under compression is often only one-third of the whole area of the cross-section, or even less. Further, the resisting moment of the compressive stresses is mainly due to the larger stresses near N, with their longer arms, and such stresses are nearly parallel to $M\ N$. Finally, and most important of all, the assumption is always on the side of safety, as will appear more fully later. The assumption is evidently near the truth for small values of β, but departs more from the truth as β increases, and possibly should be limited to values of β below some limit, say 45°, assumed arbitrarily.

* See Merriman's "Mechanics of Materials," p. 263: also "Stresses in Masonry Dams," by the writer, *Transactions*, Am. Soc. C. E., Vol. LXIV, pp. 220-221. In this article, the directions and amounts of the principal normal stresses, at various points of a horizontal section of a dam, are computed.

† *Minutes of Proceedings*, Inst. C. E., Vol. CLXXII, Session, 1907-1908, Part II.

‡ The same state of affairs exists in the so-called "beams of equal strength," having variable depth, where the ordinary theory of the books is plainly inadequate.

When the external force of Fig. 1 acts downward, the compressive area is below the neutral axis, and the reinforcement will be placed parallel to and near M N. All the compressive stresses now act parallel to the lower face, as in the common theory.

The usual hypotheses, that no tension exists in the concrete on the reinforced side of the neutral axis, and that plane sections before stress will remain plane sections after stress, will be adopted; but the latter hypothesis cannot be expected to apply very closely when β is large, particularly when it is near 90 degrees.

A general solution will now be given which includes every possible case. All special cases can be at once derived from this general solution.

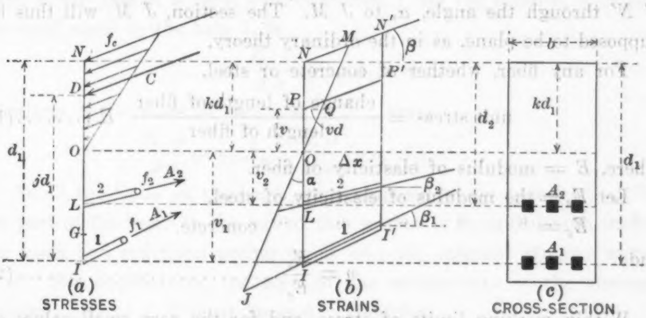

FIG. 2.

In (*a*) and (*b*), Fig. 2, are shown two longitudinal sections, and in (*c*), a section of a part of a beam subjected to stress. I N represents a section of the beam taken always parallel to the direction of the loads, which may be weights, soil reactions, earth thrusts, etc. The shear due to the loads thus acts along I N, and the moment is the same for any point of the section.

For the breadth, b, let A_1, A_2, . . ., represent the areas of the cross-sections (taken at right angles to the axes) of the bars, 1, 2, . . ., at depths d_1, d_2, . . ., respectively.

Let f_1, f_2, . . ., represent the unit stresses in the bars, 1, 2, . . ., so that the total stresses in the successive layers of bars, 1, 2, . . ., for the breadth, b, are f_1 A_1, f_2 A_2, . . ., respectively.

The angles, β, β_1, β_2, . . . (expressed in radians), are those made by the surface, N N', bars 1, bars 2, . . ., respectively, with the normal to the section, I N.

Let O be the neutral axis and D the point where the resultant, C, of the compressive forces (all acting parallel to $N\,N'$) meets $I\,N$.

Let $N\,O = k\,d_1$, $D\,I = j\,d_1$, $O\,I = v_1$, $O\,L = v_2$, etc.

$I'\,N'$ represents a section parallel to $I\,N$, Fig. 2 (*b*), and at a perpendicular distance, $\Delta\,x$, from it. The "fiber," $P\,P'$, parallel to $N\,N'$, of concrete, will be supposed to have an area equal to the section made by the plane $I\,N$, $\Delta\,a$; and the distance, $O\,P$, will be called v. Thus the area of a right section of the fiber is $\Delta\,a \cos.\,\beta$; and, if f is the unit stress on a right section of the fiber, $P\,P'$, the total compressive stress on the fiber will be $(f\,\Delta\,a \cos.\,\beta)$.

After strain, suppose the plane section, $I\,N$, rotates relatively to $I'\,N'$ through the angle, α, to $J\,M$. The section, $J\,M$, will thus be supposed to be plane, as in the ordinary theory.

For any fiber, whether of concrete or steel,

$$\text{unit stress} = \frac{\text{change of length of fiber}}{\text{length of fiber}}\;E \ldots\ldots\ldots (1)$$

where, E = modulus of elasticity of fiber.

Let E_s = the modulus of elasticity of steel,

E_c = " " " " " concrete,

and,

$$n = \frac{E_s}{E_c} \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (2)$$

Within working limits of stress, and for the very small values of α corresponding to very small values of $\Delta\,x$, the change of length of $P\,P' = P\,Q = v\,\alpha \sec.\,\beta$, very nearly*; hence the unit stress, f, on this fiber, $P\,P'$, by Equation 1 is

$$f = \frac{P\,Q}{P\,P'}\,E_c = \frac{v\,\alpha \sec.\,\beta}{\Delta\,x \sec.\,\beta}\,E_c = \frac{v\,\alpha}{\Delta\,x}\,E_c.$$

Hence, as this unit stress on a right section of the fiber acts on the right sectional area, $\Delta\,a \cos.\,\beta$, the total stress on the fiber is

$$\frac{v\,\alpha}{\Delta\,x}\,E_c\,(\Delta\,a \cos.\,\beta).$$

and its component perpendicular to $I\,N$ is

$$\frac{E_c\,\alpha \cos.^2 \beta}{\Delta\,x}\,(v\,\Delta\,a).$$

* In the triangle, $P\,O\,Q$, by the law of sines, $P\,Q = \dfrac{v \sin.\,\alpha}{\cos.\,(\alpha + \beta)}$. As α tends toward zero, this approaches $\dfrac{v\,\alpha}{\cos.\,\beta} = v\,\alpha \sec.\,\beta$.

The sum of such components on the compressed area of depth, $k\, d_1$, and breadth, b, is

$$\frac{E_c\, \alpha \cos.^2 \beta}{\Delta x} \sum_0^{kd_1} (v\, \Delta\, a) = \frac{E_c\, \alpha \cos.^2 \beta}{\Delta x} \left(\frac{1}{2}\, b\, k^2\, d_1^2 \right),$$

since $\sum_0^{kd_1} (v\, \Delta\, a) =$ the statical moment of the area under compression about the neutral axis $= b\, k\, d_1 \frac{1}{2}\, k\, d_1$.

For the layer of bars 1, at I, similarly, the unit stress is

$$f_1 = \frac{J\, I}{I\, I'} E_s = \frac{v_1\, \alpha \sec.\, \beta_1}{\Delta x \sec.\, \beta_1} E_s = \frac{E_c\, \alpha}{\Delta x} (n\, v_1).$$

Also, as the area of a right section of bars 1, for the breadth, b, is A_1, the total stress in the bars 1, is

$$\frac{E_c\, \alpha}{\Delta x} (n\, v_1\, A_1).$$

Similarly, the stresses in bars 2, 3, . . ., are

$$\frac{E_c\, \alpha}{\Delta x} (n\, v_2\, A_2),\ \frac{E_c\, \alpha}{\Delta x} (n\, v_3\, A_3),\ . . .$$

As all the loads on the beam were supposed to act parallel to $I\, N$, the part of the beam to the left of this section is in equilibrium under the loads and reactions acting on it and the internal stresses along $I\, N$. For equilibrium, the sum of the components of the stresses perpendicular to $I\, N$ must be zero. Therefore,

$$\frac{E_c\, \alpha}{\Delta x} \cos.^2 \beta \left(\frac{1}{2}\, b\, k^2\, d_1^2 \right)$$
$$= \frac{E_c\, \alpha}{\Delta x}\, n\, (v_1\, A_1 \cos.\, \beta_1 + v_2\, A_2 \cos.\, \beta_2 + . . .).$$

From Fig. 2,

$$v_1 = d_1 - k\, d_1,\ v_2 = d_2 - k\, d_1,\ . . .;$$

hence, on substituting these values, striking out the common factor, and reducing, we derive,

$$\frac{1}{2} \cos.^2 \beta\, b\, d_1^2\, k^2 + n\, d_1\, (A_1 \cos.\, \beta_1 + A_2 \cos.\, \beta_2 + . . .)\, k$$
$$= n\, (d_1\, A_1 \cos.\, \beta_1 + d_2\, A_2 \cos.\, \beta_2 + . . .) \ldots\ldots\ldots (3)$$

From this quadratic in k, the value of k is computed, and thus $k\, d_1 = O\, N$ can be found and the neutral axis located. Also, as the compressive stresses are uniformly varying, $D\, N = \frac{1}{3}\, O\, N$; therefore, $j\, d_1 = d_1 - \frac{1}{3}\, k\, d_1$; and

$$j = 1 - \frac{1}{3}\, k \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (4)$$

The Resisting Moment, M_s, of the Steel.—The moment, M, at the section, $I\ N$, due to the external forces, is equal to the resisting moment of the stresses acting along the section. Calling the perpendicular distances from D to bars 1, 2, . . ., p_1, p_2, . . ., respectively,

$$M_s = f_1\ A_1\ p_1 + f_2\ A_2\ p_2 + \ldots, \ldots\ldots\ldots\ldots (5)$$

where, $p_1 = j\ d_1 \cos. \beta_1$, $p_2 = D\ L \cos. \beta_2$, etc.

Now, as $f_1 = \frac{E_c\ \alpha}{\Delta\ x}\ n\ v_1$, $f_2 = \frac{E_c\ \alpha}{\Delta\ x}\ n\ v_2$, . . ., it follows that

$$f_2 = \frac{v_2}{v_1}\ f_1,\ f_3 = \frac{v_3}{v_1}\ f_1, \ldots, \ldots\ldots\ldots\ldots (6)$$

or the unit stresses in the bars vary directly with the distances from the neutral axis. The unit stresses in the interior bars will thus always be less than f_1, so that such an arrangement of bars is uneconomical.

On substituting Equation 6 in Equation 5,

$$M_s = f_1\ \left(A_1\,p_1 + \frac{v_2}{v_1}\ A_2\,p_2 + \frac{v_3}{v_1}\ A_3\,p_3 + \ldots\right) \ldots\ldots\ldots (7)$$

If preferred, after locating the point, D, on a drawing, the perpendiculars, p_1, p_2, . . ., can be measured to scale; otherwise, they may be computed readily by the formulas given.

If the resisting moment of the steel, M_s, is less than that of the concrete, M_c, for assigned maximum unit stresses, then the moment, M, of the external forces is put equal to the right member of Equation 7, the value of f_1 ascertained, and, from Equation 6, the values of f_2, f_3, . . ., are computed. The stresses in bars 1, 2, . . ., are thus $f_1\ A_1$, $f_2\ A_2$, . . .

Otherwise, if a certain value is assigned to f_1, as 16 000 lb. per sq. in., and A_2, A_3, . . ., are assumed, from Equation 7, A_1 can be computed. For rough computations, A_2, A_3, . . ., may often be ignored, in which case we can write,

$$M_s = f_1\ A_1\ p_1 = f_1\ A_1\ j\ d_1 \cos. \beta_1.$$

The Resisting Moment, M_c, of the Concrete.—To compute M_c, the position of the resultant, R, of the stresses in the bars, must first be found. The magnitudes of the forces acting on the bars 1, 2, 3, . . ., are

$$f_1\,A_1,\ f_1\,\frac{v_2}{v_1}\ A_2,\ f_1\ \frac{v_3}{v_1}\ A_3, \ldots,$$

and, as these are proportional to f_1, the direction and line of action of R are the same for any value of f_1 and hence for $f_1 = 1$.

Let $H =$ the component of R perpendicular to $I\,N$ when $f_1 = 1$; then

$$H = A_1 \cos.\,\beta_1 + \frac{v_2}{v_1} A_2 \cos.\,\beta_2 + \cdots$$

Suppose the resultant cuts $I\,N$ at G; then, taking moments about D,

$$H \cdot D\,G = A_1 p_1 + \frac{v_2}{v_1} A_2 p_2 + \frac{v_3}{v_1} A_3 p_3 + \cdots$$

The right member, presumably, has already been computed in applying Equation 7; hence $D\,G$ is quickly ascertained and the point, G, located.

Call the maximum unit stress on the concrete at N, f_c; the unit stress on the fiber, $P\,P'$, at P is thus $\frac{f_c}{k\,d_1}\,v$. This acts on the area $(\Delta\, a \cos.\,\beta)$; hence the stress on the fiber is

$$\frac{f_c}{k\,d_1}\, v\, \Delta\, a \cos.\,\beta,$$

and the sum of such stresses is

$$C = \frac{f_c}{k\,d_1} \cos.\,\beta \sum_0^{kd_1} (v\,\Delta\, a) = \frac{1}{2}\,\frac{f_c}{k\,d_1} \cos.\,\beta\, b\,(k\,d_1)^2.$$

Therefore, $C = \frac{1}{2} f_c\, b\, k\, d_1 \cos.\,\beta$.

Taking moments about G,

$$M_c = \frac{1}{2} f_c\, b\, k\, d_1 \cos.^2 \beta\, \overline{D\,G} \ldots\ldots\ldots\ldots\ldots\ldots (8)$$

If, for assigned maximum values of f_1 and f_c, $M_s > M_c$, the beam is over-reinforced and M is placed equal to the right member of Equation 8, as its strength is now limited by that of the concrete. This case rarely occurs in practice.

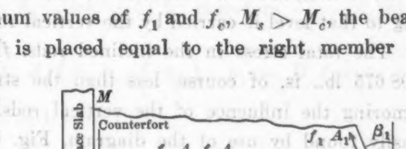

FIG. 3.

As an illustration of the application of the formulas, take the counterfort, $B\,M$, Fig. 3, attached to the face-slab, $N\,M$, and suppose the counterfort to be subjected to a horizontal earth thrust of 123 750 lb., acting to the left and 9.06 ft. above N, giving a bending moment at N of 13 454 100 in-lb. The section, $N\,B$, corre-

sponding to $N\ I$ of Fig. 2, is taken parallel to the load (the earth thrust), and is therefore horizontal.

The width of the counterfort is $b = 18$ in. The inclined bars have a total sectional area $= A_1 = 9.45$ sq. in., and the vertical bars, a common area, $A = 0.784$ sq. in. Using the foregoing notation, $\beta_1 = 23° 58'$, $\beta_2 = \beta_3 = \ldots = \beta_7 = 0$. The distances, d, were measured from N, or from the front face of the vertical slab: $d_1 = 128$, $d_2 = 108$, $d_3 = 100$, $d_4 = 92$, $d_5 = 76$, $d_6 = 60$, $d_7 = 44$, all in inches. Assume $n = 15$.

On substituting known values in Equation 3, we derive $k = 0.311$. Therefore, $j = 1 - \frac{1}{3}\ k = 0.896$; whence $N\ O = k\ d_1 = 39.8$ in., $D\ B = j\ d_1 = 114.7$ in.; also, $N\ D = \frac{1}{3}\ N\ O = 13$ in.

On subtracting $N\ O = 40$ from $d_1, d_2, \ldots$, we derive v_1, v_2, etc. The perpendiculars, $p_1, p_2, \ldots$, from D on bars 1, 2, . . ., are $p_1 = j\ d_1 \cos. \beta_1 = 105$, $p_2 = d_2 - N\ D = 95$, . . ., respectively.

From Equation 7 we have, $13\,454\,100 = 1\,164\ f_1$; whence $f_1 = 11\,500$ lb. per sq. in.; from Equation 6, $f_2 = 8\,970$, . . ., $f_7 = 575$ lb. per sq. in.

As the weight of the heel-slab must be carried by the rods, the areas and spacing of the vertical rods were designed to carry their proportionate part of the weight of the heel-slab. The stresses corresponding are found to be in excess of those due to the moment, M. This excess is taken up by the bond stress in a short distance above $N\ B$, so that, above a certain level, only the moment stress corresponding to that level is carried by the vertical rods.

The total stress in the inclined rods, $f_1\ A_1 = 11\,500 \times 9.45 = 108\,675$ lb., is, of course, less than the stress, 127 000 lb., found by ignoring the influence of the vertical rods. This last stress is most easily found by use of the diagram, Fig. 6, and Equation 11, given later.

This example of the counterfort has been given more for the purpose of gaining an idea of the actual stresses involved than of urging the adoption of the more refined method in practice.

If the diameter of a bar is to be some multiple of $\frac{1}{8}$ in., there may be no saving by the use of the more exact method. It must be remembered, too, that the vertical bars are not always bonded securely in the base-slab, the earth thrust may also be much increased in times

of heavy rains, where the filling is not adequately drained; and, further, the foundation may be more yielding than estimated.

In the next example, Fig. 4, representing the heel of a T-wall with a fillet, the wall being on the point of overturning, the exact method seems advisable.

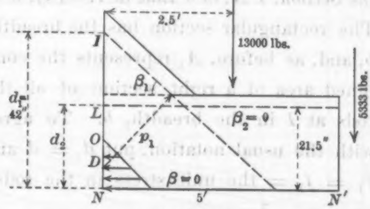

FIG. 4.

The total moment at the section, $N\ I$, due to the two forces shown, is

$$M = (13\,000 \times 2.5 + 5\,333 \times 5)\ 12 = 709\,992 \text{ in-lb.}$$

The reinforcement, shown by the broken lines, for both inclined and horizontal bars, consists of $\frac{7}{8}$-in. square bars, 8 in. from center to center, corresponding to $A_1 = A_2 = 1.15$ sq. in. for a breadth of $b = 12$ in.

Assuming $n = 15$, $\beta_1 = 43°\ 10'$, $\beta = \beta_2 = 0$, $d_1 = 42$, $d_2 = 21.5$, and substituting in Equation 3,

$$\frac{1}{2}\ b\ d_1{}^2\ k^2 + n\ A_1\ d_2\ (\cos.\ \beta_1 + 1)_k = n\ A_1(d_1 \cos.\ \beta_1 + d_2)$$

we find, after solution,

$$k = 0.238\ ;\ \text{therefore } j = 1 - \frac{1}{3}\ k = 0.921,$$

$$N\ O = k\ d_1 = 10 \text{ in., } D\ I = j\ d_1 = 39 \text{ in., } N\ D = 3.33 \text{ in.,}$$

$$v_1 = d_1 - kd_1 = 32,\ v_2 = d_2 - kd_1 = 11.5\ ;\ \text{therefore } \frac{v_2}{v_1} = 0.361.$$

By Equation 7, $M_s = f_1\ A_1\left(p_1 + \frac{v_2}{v_1}\ p_2\right)$, $p_1 = D\ I \cos.\ \beta_1$

$$= 28.4,\ p_2 = 18.2;$$

$$\text{therefore } M = 710\,000 = 1.15\ (18.2 + 6.57)\ f_1 = 40\ f_1;$$

therefore $f_1 = 17\,750$ lb. per sq. in., $f_2 = \frac{v_2}{v_1}\ f_1 = 6\,380$ lb. per sq. in.

Where the foundation is good, there can be only a very small moving over of the wall, so that the friction force, 5 333 lb., at N' can be neglected and the soil reaction included. In this particular example (not given in full here) the new values of f_1 and f_2, thus found, are only four-tenths of those given previously.

Special Case.—Where $\beta = 0$ and All the Rods Lie in One Plane Which Meets the Section, I N, in a Line at I.—Fig. 5.— The rectangular section has the breadth, b, and, as before, A_1 represents the combined area of a right section of all the rods at I in the breadth, b. To agree with the usual notation, put $d_1 = d$ and $f_1 = f_s =$ the unit stress in the rods. Equation 3 now reduces to

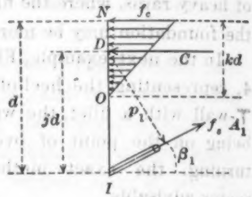

FIG. 5.

$$\frac{1}{2}\, b\, d^2\, k^2 + nd\, A_1 \cos.\, \beta_1\, k - nd\, A_1 \cos.\, \beta_1 = 0.$$

Placing $p = \dfrac{\text{steel area}}{\text{concrete area}} = \dfrac{A_1}{b\,d}$, and dividing by $\dfrac{1}{2}bd^2$,

$$k^2 + 2\, n\, p \cos.\, \beta_1\, k - 2\, n\, p \cos.\, \beta_1 = 0,$$

therefore $k = -\, n\, p \cos.\, \beta_1 + \sqrt{(n\, p \cos.\, \beta_1)^2 + 2\,(n\, p \cos.\, \beta_1)}$ ..(9)

when $\beta_1 = 0$, this reduces to the usual formula for prismatic beams,

$$k = -\, n\, p + \sqrt{(n\, p)^2 + 2\,(n\, p)} \quad\ldots\ldots\ldots\ldots(10)$$

In Fig. 6, the values of k and $j = 1 - \frac{1}{3}k$, are given as ordinates to the dotted curves for various percentages of steel and values of β_1, varying from 0° to 40°, assuming $n = 15$.

The resisting moment of the steel is found by taking moments about D,

$$M_s = f_s\, A_1 \cos.\, \beta_1\, j\, d = f_s\, A_1\, p_1 \quad\ldots\ldots\ldots\ldots(11)$$

where $p_1 =$ the perpendicular distance from D on the bar.

The resisting moment of the concrete is found by taking moments about I,

$$M_c = \frac{1}{2} f_c\, b\, k\, d\, j\, d = \frac{1}{2} f_c\,(k j)\, b\, d^2 \quad\ldots\ldots\ldots(12)$$

For assigned maximum working values of f_s and f_c, the least resisting moment is equated to the moment of the external forces.

In using Fig. 6, note that p is not the percentage of steel, but $\frac{1}{100}$ of the percentage.

Resuming the example of the counterfort, Fig. 3, what will be the result of ignoring the vertical rods? With $A_1 = 9.45$ sq. in. and as

FIG. 6.

the area of the base or section, $N\ B = 128 \times 18 = 2\,304$ sq. in., $p = \frac{9.45}{2\,304} = 0.004$, or the steel percentage is 0.4. Using Fig. 6, with $\beta_1 = 24°$ and the steel percentage 0.4,

$$j = 0.906;\ \text{therefore}\ jd = 0.906 \times 128 = 116.$$

Hence, as the moment of the earth thrust was given as $M = 13\,454\,100$ in-lb., by Equation 11,

$$f_s\ A_1 \times 116 \times 0.914 = 13\,454\,100;$$

therefore $f_s\ A_1$ = the stress in the inclined rods = 127 000 lb. With $A_1 = 9.45$, as assumed, $f_s = 13\,400$ lb. per sq. in., in place of 11 500 lb. per sq. in., found before, the vertical rods being included.

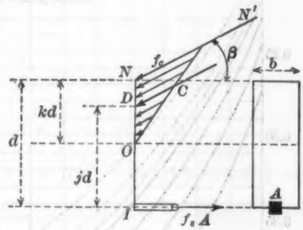

FIG. 7.

Special Case.—Where the Rods Lie in One Plane, for Which $\beta_1 = 0$, But β is Not Zero.—Fig. 7.—Putting d for d_1, and A for A_1, Equation 3 reduces to

$$\cos.^2 \beta\ bd\ k^2 + 2\ n\ A\ k - 2\ n\ A = 0.$$

Therefore, as before, putting $p = \frac{A}{b\ d}$,

$$k = \frac{1}{\cos.^2 \beta}\left[-(n\ p) + \sqrt{(n\ p)^2 + 2\ (n\ p)\cos.^2 \beta}\right] \ldots\ldots (13)$$

In Fig. 6, the full lines give the values of k and $j = 1 - \frac{1}{3}\ k$, corresponding to $n = 15$ and to various values of β and percentages of steel. Equation 7, in this case, reduces to

$$M_s = f_s\ A\ jd \ldots\ldots\ldots\ldots\ldots\ldots\ldots (14)$$

Also, as $D\ G = D\ I = jd$, Equation 8 becomes

$$M_c = \frac{1}{2}\ f_c\ (k\ j)\ bd^2 \cos.^2 \beta \ldots\ldots\ldots\ldots\ldots (15)$$

If, in Fig. 7, we write $p' = d \cos.\ \beta$ = the perpendicular from I on $N\ N'$ produced,

$$M_c = \frac{1}{2}\ f_c\ (k\ j)\ b\ p'^2 \ldots\ldots\ldots\ldots\ldots\ldots (16)$$

The product, kj, varies with β. In Table 1 the values of $(kj) \cos.^2 \beta$, are given for various values of p and β. The values for $\beta = 0$, pertain to a prismatic beam.

TABLE 1.—VALUES OF $(k\,j) \cos.^2 \beta$.

$100\,p$	0.2	0.6	1.0	1.6	2.0
$\beta = 0$	0.200	0.303	0.359	0.411	0.441
$\beta = 10°$	0.199	0.299	0.352	0.403	0.427
$\beta = 20°$	0.186	0.281	0.329	0.376	0.397
$\beta = 30°$	0.169	0.251	0.294	0.333	0.351
$\beta = 40°$	0.145	0.212	0.246	0.276	0.289

It is seen from the tabular values and Equation 15, that M_c as given by Equation 15 is always less for $\beta > 0$ than for $\beta = 0$.

In the ordinary theory, given in textbooks on "strength of materials", for homogeneous "beams of equal strength" with variable depth, vertically loaded, it is assumed that at any vertical section the theory for a prismatic beam applies; which entails the postulate that the bending stress at any point of the section acts perpendicular to it. The theory is thus inadequate to express the facts, because it was shown, in the beginning of this paper, that the stress at N, Fig. 7, acts parallel to the face, $N\ N'$.

This common theory, if extended to reinforced beams of the type shown by Fig. 1, is on the side of danger, for it would give, for any β, the value of M_c from Equation 15 corresponding to $\beta = 0$. As a matter of fact, the compressive stresses, Fig. 7, act parallel to $N\ N'$ only at N, and gradually take a less inclination to the normal to $I\ N$, as points are taken farther down the joint. Thus M_c, as given by Equation 15 for $\beta > 0$, is less than the true value, and is thus on the side of safety. The true value lies between that given by Equation 15 for the assumed value of β, supposed to be greater than zero, and the value for $\beta = 0$, doubtless lying much nearer the former value than the latter because M_c is affected to a greater extent by the larger stresses near N, which are nearly parallel to $N\ N'$ and have longer arms, than by those smaller stresses nearer the neutral axis, with their shorter arms.

The case where $\beta = 0$, $\beta_1 = 0$, leads to the ordinary formulas for a prismatic reinforced beam, for which a valuable working diagram was first given* by Arthur W. French, M. Am. Soc. C. E.

* *Transactions*, Am. Soc. C. E., Vol. LVI, 1906, p. 362.

Maximum Shearing Stresses.—Let $I\ N\ N'\ I'$, Fig. 8, represent a part of the beam lying between two sections, $I\ N$, $I'\ N'$, perpendicular to the plane of the paper and parallel to the direction of the loads, and dx apart. These sections are rectangular, having the breadth b. The beam is supposed to be reinforced with the rods $I\ I'$, $L\ L'$, $S\ S'$, . . .

Let V and V' denote the shears due to the loading C and C', the resultants of the compressive stresses, and T and T', the resultants of the tensions in the bars, at the sections, $I\ N$, $I'\ N'$, respectively.

The part of the beam, $I\ N\ N'\ I'$, is in equilibrium under the action of these forces, with the directions given by the arrows, its own weight and load; but as the weight and load are equal to an expression that contains dx as a factor, it is infinitesimal, compared with the forces, and is neglected. It is to be observed, also, that T' is supposed to act in the same line as T, because it approaches this position indefinitely as dx tends toward zero.

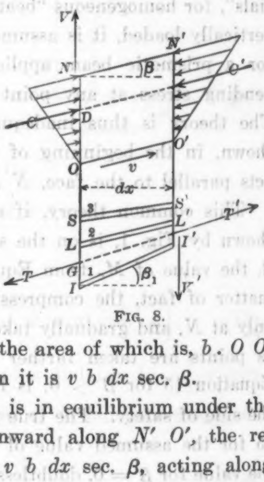

FIG. 8.

Suppose that T meets the section, $I\ N$, at G, and takes moments about G of the forces in equilibrium:

$$(C' - C) \cos. \beta\ \overline{D\ G} = V'\ dx.$$

Taking the neutral surface as parallel to the surface, $N\ N'$, and calling v the unit shear along this neutral surface, the area of which is, $b \cdot O\ O' = b\ dx \sec. \beta$, the total shearing stress on it is $v\ b\ dx \sec. \beta$.

The prism, $N\ O\ O'\ N'$, of breadth, b, is in equilibrium under the shears, acting upward along $O\ N$, downward along $N'\ O'$, the resultants, C, C', and the shearing stress, $v\ b\ dx \sec. \beta$, acting along $O\ O'$. Hence the algebraic sum of the horizontal components is zero. Therefore,

$$(C' - C) \cos. \beta = (v\ b\ dx \sec. \beta) \cos. \beta = v\ b\ dx.$$

Substituting this value in the preceding equation, dividing by dx, and then taking the limit, as dx approaches zero and V' approaches V indefinitely, it is found that

$$v = \frac{V}{b\ \overline{D\ G}} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots (17)$$

The point, G, can be found without knowing the stresses in the bars, as explained previously. This unit shear, v, exists from the neutral surface to the bars nearest to it.

The case most frequently met is where all the steel reinforcement is placed in the plane through $I\ I'$, perpendicular to the plane of the paper. For this case, G coincides with I and $D\ G = j\ .\ I\ N = jd$, putting $I\ N = d$. Therefore,

$$v = \frac{V}{jd\ .\ b} \qquad (18)$$

From Fig. 6, j can be found when either β or β_1 is zero, or when both are zero. In the latter case, Equation 18 is a well-known formula, and for approximate values, $j = \frac{7}{8} = 0.875$ is often used.

The maximum shearing stress given by the last equation remains the same for points between the neutral surface and the steel. Above the neutral surface, it decreases, by the usual parabolic law, to zero at N. The unit shear, v, acts parallel to $N\ N'$.

Bond Stress.—In Fig. 8, first suppose the steel bars to lie only in the plane, $I\ I'$. For the breadth, b, let the total tension in the bars at I be t_1, acting in the direction $I'\ I$, and the corresponding tension at I' be t_1', acting in the direction $I\ I'$. The increment of stress $(t_1' - t_1)$, is transmitted by the bond between the concrete and the steel.

Let $u =$ this bond stress per square inch of surface of the rods;

$o =$ the surface area of one bar for 1 in. of length (equal to the perimeter);

$\Sigma\, o =$ the surface area of all the bars in the width, b, for 1 in. of length.

In the length, $I\ I' = dx$ sec. β_1, the total area is $I\ I'\ \Sigma\ o$, and the total bond stress is $u\ dx$ sec. $\beta_1\ \Sigma\ o = t_1' - t$.

Taking moments about D, of the forces, V, V', C, C', t_1, t_1', in equilibrium,

$$(t_1' - t) \cos.\ \beta_1\ I\ D = u\ dx\ \Sigma\ o\ I\ D = V'\ dx.$$

Dividing by dx, taking limits as dx approaches zero, and replacing $I\ D$ by $j\ d$,

$$u = \frac{V}{j\ d\ \Sigma\ o} \qquad (19)$$

In this formula, $d = N I$, and j is to be found by the diagram, Fig. 6, or by previous methods. When $\beta_1 = 0$, $\beta = 0$; the approximate value, $\frac{7}{8}$, is often used.

The formulas for both shear and bond stresses, Equations 18 and 19, are of the usual form, corresponding to $\beta_1 = \beta = 0$. They are more general than for the latter case, and it is only necessary to substitute the proper value of j for the values of β and β_1 assumed to obtain the proper values of the stresses.

Where there are several layers of bars, as at $I\,I'$, $L\,L'$, $S\,S'$, . . ., let u_1, u_2, . . ., indicate the unit bond stresses and $\Sigma\, o_1$, $\Sigma\, o_2$, . . ., the areas per linear inch of surface of the rods, for the width, b, for the respective bars; then the total bond stresses at $I\,I'$, $L\,L'$, . . ., are

$$u_1\, I\,I'\, \Sigma\, o_1,\ u_2\, L\,L'\, \Sigma\, o_2,\ \ldots,$$

which are equal, respectively, to $(t_1' - t_1)$, $(t_2' - t_2)$, . . ., the subscripts referring to bars 1, 2, . . ., at $I\,I'$, $L\,L'$, ...

Taking moments about D and proceeding as before, we easily derive,

$$\overline{I\,D}\, u_1\, \Sigma\, o_1 + \overline{L\,D}\, u_2\, \Sigma\, o_2 + \overline{S\,D}\, u_3\, \Sigma\, o_3 + \ldots = V.$$

Now, the unit bond stress in any rod is proportional to the unit elongation of the rod, or to its unit stress, which varies with the distance from O (See Equation 6); hence, for the same loading,

$$u_2 = u_1 \frac{O\,L}{O\,I},\ u_3 = u_1 \frac{O\,S}{O\,I},\ \ldots \qquad (20)$$

Therefore the previous equation reduces to

$$u_1 \left[I\,D\, \Sigma\, o_1 + L\,D\, \frac{O\,L}{O\,I}\, \Sigma\, o_2 + S\,D\, \frac{O\,S}{O\,I}\, \Sigma\, o_3 + \ldots \right] = V \quad (21)$$

From this equation, u_1 is found; then, from Equation 20, u_2, u_3, . . .

If the interior bars are ignored, and u_1 is found from the simple formula, Equation 19, to be within safe limits, it follows that the true bond stresses on all the bars are less, and are therefore within safe limits.

The application of Equations 18 and 19 is obvious. As Equations 17 and 21 are unusual forms, it may prove of service to the computer to give a numerical illustration. Let it be proposed, therefore, to find

the shear and bond stresses for the heel-slab with the fillet, Fig. 4, already considered.

The total shear at $N\,I$, for $b = 12$ in. length of wall, is $V = 18\,333$ lb. The tension in the bar which makes the angle, $\beta_1 = 43^\circ\ 10'$, with the horizontal, is $f_1\ A_1$, and that in the horizontal bar is $f_1 \dfrac{O\,L}{O\,I} A_2 = f_1 \dfrac{11.5}{32} A_2 = 0.361\ f_1\ A_2$. As $A_1 = A_2$, these tensions are in the ratio, $1:0.361$, and the point, G, where the resultant of the two tensions cuts $N\,I$, is the same as for two forces of magnitudes 1 and 0.361, having the same positions and directions.

Let $H =$ the sum of the horizontal components of the two forces supposed. Therefore

$$H = 1 \times \cos.\ \beta_1 + 0.361 = 1.090.$$

Taking moments about D,

$$\begin{aligned} H\,.\ \overline{D\ G} &= 1 \times \cos.\ \beta_1 \times \overline{D\,I} + 0.361 \times \overline{D\,L} \\ &= 0.729 \times 39 + 0.361 \times 18.2 = 34.97. \end{aligned}$$

Therefore, $D\ G = 32.1$ in., and the maximum shear is

$$v = \frac{V}{b\,.\,D\ G} = \frac{18\,333}{12 \times 32.1} = 47.6 \text{ lb. per sq. in.}$$

Both the inclined and horizontal reinforcement consists of ⅞-in. square rods, spaced 8 in. from center to center. Therefore,

$$\Sigma\ o_1 = \Sigma\ o_2 = \frac{12}{8}\ (3.5) = 5.25 \text{ for } b = 12 \text{ in.}$$

Also, from previous computations,

$$I\ D = 39,\ L\ D = 18.2,\ O\ L = 11.5,\ O\ I = 32 \text{ in.}$$

Therefore, by Equation 21, the unit bond stress, u_1, on the inclined rods is given by

$$u_1 \times 5.25 \left[39 + \frac{11.5 \times 18.2}{32} \right] = 18\,333.$$

Therefore, $u_1 = 76.7$ lb. per sq. in., and the unit bond stress on the horizontal rods is

$$u_2 = \frac{O\ L}{O\ I}\ u_1 = \frac{11.5}{32} \times 76.7 = 27.5 \text{ lb. per sq. in.}$$

In what precedes, there is much that may appear novel. The problems that occur in practice pertain to two different classes of beams.

In those of the first class, illustrated by Figs. 3 and 4, the section, *I N*, is taken perpendicular to the face on the compressive side, and the bending stresses there act perpendicularly to the section, as in the ordinary theory. In beams of the second class, as in Fig. 1, the section, *I N*, is not perpendicular to the face on the compressive side, and the compressive stresses are all assumed to act parallel to the face. It is possible that this assumption, alone, will be open to criticism, for, accepting the hypothesis, all the results follow readily from simple mechanical laws.

The writer invites a careful criticism of this hypothesis, with the accompanying deductions. A strict solution of beams of the second class is doubtless impracticable, but the writer believes that he has effected a practical solution which is on the side of safety and may commend itself to the practitioner.

DISCUSSION

A. C. JANNI, M. AM. SOC. C. E. (by letter).—Before entering into any discussion on the opportunity and legitimacy of the assumption on which this work hinges, the writer wishes to call the author's attention to a little mathematical "license" which he took in simplifying the expression, $P\,Q = \frac{v \sin.\alpha}{\cos.(\alpha + \beta)}$,* because it undermines, perhaps, the whole mathematical "make-up" of all the formulas which depend on that *"lapsus calami"*. Mr. Janni.

There is no doubt that, as α tends toward zero, $\sin.\alpha$ may be substituted for α; this simplification being entirely legitimate; but, if α tends toward zero, the expression $\cos.(\alpha + \beta)$ does not tend toward $\cos.\beta$, by any means.

The author knows that $\cos.(\alpha + \beta)$ is purely a symbol of a certain operation to be performed, and is not an actual value; its value is given by $\cos.\alpha \cos.\beta - \sin.\alpha \sin.\beta$, and it is on this latter that he may operate his simplification. Thus his $P\,Q = v\,\alpha \sec.\beta$ should become $P\,Q = \frac{v\,\alpha}{\cos.\beta - \alpha \sin.\beta}$, when it is assumed that α tends toward zero, to be a mathematically correct simplification.

Concerning the assumption adopted by the author in order to find a "workable formula" for the compressive stress in concrete, and also some of his statements, the writer cannot quite agree. Two questions are before him, namely:

1. Do we need that formula?
2. Is that formula worked out correctly?

It is the writer's opinion that neither of these questions can be answered in the affirmative.

Theory is quite competent to take care of a design of a wedge-shaped beam, if necessary, despite what the author says. If the cross-section of a wedge-shaped concrete beam is rectangular, and the angle, β, is not large, the common formula for bending is sufficiently good to give the maximum compressive stress in the concrete.

It is a fact that the formula entails the truth—which, by the way, is not a postulate—demonstrated by Saint-Venant, that all bending stresses at any point act perpendicularly to the cross-section; but this, in the case where β is not very large, does not prevent the formula from giving a result sufficiently near to the truth to insure the maximum stress.

That the direction of the maximum stress, in the case of Fig. 1, is parallel to the top, $N\,M$, of the beam, and on which the author lays

* See foot-note, p. 748.

Mr. Janni.

so much stress, is, nowadays, mathematically ascertained.* In the case of a dam design, that direction is of capital importance, and the failure to recognize it, or the overlooking of it, in the design of some dams, has often been the cause of loss of thousands of innocent lives and, perhaps, millions of dollars. In a wedge-shaped beam, however (or in a counterfort), the conditions are such that the direction of the maximum compressive stress can be ignored in most cases.

If the cross-section of the wedge-shaped beam is not rectangular, then, with proper limitations, the usual formula to determine the principal stresses, reported in many textbooks, can be used. This formula is, precisely, designed for a beam by taking as unknown quantities certain inclined stresses, called "principal stresses", instead of the normal stresses in that section, and, really, this is the most logical way of designing a beam, although the common practice, for opportune reasons, follows that of the bending and shear formulas.

Winkler, in 1867, as far as the writer knows, wrote on this subject, and, after him, Culmann, Ritter, Guidi, and others treated the same question; so that the conception cannot appear novel, as the author seems to think, at least judging by some of his remarks.

If, finally, the inclination of *N M*, Fig. 1, is large, then Grashof's formula, with due limitations for the case of reinforced concrete, may be used.

In view of all the foregoing considerations, the writer thinks that there is no need of a formula for the case in point, and that, after all the arbitrary assumptions of the author in reaching his "workable formula", admitting its correct mathematical "make-up", its results are much farther from the truth than those given by the existing formulas, which, in all cases, are very reliable.

It is necessary, accordingly, to take into consideration the author's assumption in finding that formula, and, as a consequence, its mathematical reliability.

As the writer said before, it is very well known that the extreme top compressive stress is parallel to the beam top as, disregarding the friction on the soil, Fig. 1, the maximum tensile stress is parallel to the bottom, *L I*.

The author states that the maximum tensile stress at that region of the beam would be parallel to *L I*, if the beam were a homogeneous one.

Even if the beam were homogeneous, if friction is not disregarded, the maximum tensile stress, at the bottom of the beam, is not parallel to the bottom face.

When the beam is heterogenous, as in the author's case, equilibrium conditions do not change, if friction is included; the only dif-

---

* M. Levy, *Annales des Ponts et Chaussées*, 1897; and F. Platzmann, *Ueber den Querschnitt der Staumauern*, Leipzig, 1908.

Mr. Janni.

ference being that, as usual, the tension in concrete is disregarded, so that the designer is inclined to disregard its direction, also, unless it is not a case of scientific research.

Now, the maximum compressive stress being parallel to the top, and the maximum tensile stress (always disregarding friction) being parallel to the bottom, the intermediate bending stresses, the author says, change their direction gradually from $N\,M$ to $L\,I$, Fig. 1. As a matter of fact, those intermediate bending stresses do not change their direction gradually in the way the author means. Fig. 9 gives an idea of the behavior of the internal stresses in the cross-section, $N\,I$, on account of the angle β. The author, however, states that, for the purpose of finding "workable formulas", he must assume that the intermediate compressive bending stresses be parallel to the maximum compressive bending stress. Such an assumption cannot be justified, when it is well known how those stresses act, and a designer knows how to determine them. Their direction, which is not constant for all, is a function of the angle, β, and not of cos. β, and their position is farther and farther from the author's assumption as β increases.

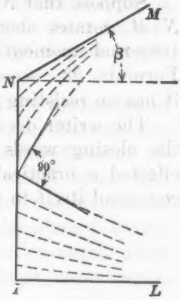

FIG. 9.

Apart from this assumption made by the author, which does not seem justifiable to the writer from any point of view, it is interesting to study the formula itself.

Formula 8, which, according to the author, gives the maximum compressive stress in the concrete, will be taken into consideration. For the sake of clearness, the writer will compare the theoretical formula for bending in a beam of constant cross-section, which, when β is not very large, may be used without any fear of going astray, with the author's formula for the same kind of stresses in a wedge-shaped beam, using for both the same lettering, Fig. 10.

The theoretical formula for bending in a beam of constant rectangular cross-section is

$$f_c = \frac{2\,M}{b\,y\left(h - \frac{1}{3}\,y\right)} = Q \quad \ldots\ldots\ldots\ldots\ldots (22)$$

The author's formula for bending in a wedge-shaped beam is

$$f_c = \frac{2\,M}{b\,y\left(h - \frac{1}{3}\,y\right)\cos.^2\beta} = \frac{Q}{\cos.^2\beta} \quad \ldots\ldots\ldots (23)$$

It is plain, as the author says, that Formula 23, for $\beta = 0°$, becomes Formula 22.

Mr. Janni. Formula 23, however, as given by the writer, presents some other information rather interestingly.

Suppose that $N\ I$, Fig. 10, be a constant section, and that the line, $N\ M$, rotates about N, the angle, β, increasing gradually while M (external moment), keeps constant, the section, $N\ I$, according to Formula 23, becomes weaker and weaker, until, when $\beta = 90°$, it has no resisting power whatever.

The writer does not think any comment necessary, except to recall the closing words of the paper: "The writer believes that he has effected a practical solution which is on the side of safety and may commend itself to the practitioner."

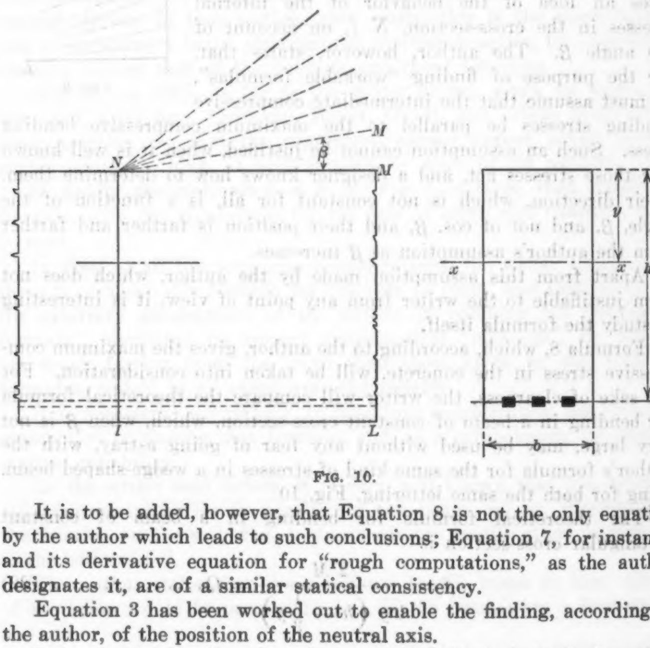

FIG. 10.

It is to be added, however, that Equation 8 is not the only equation by the author which leads to such conclusions; Equation 7, for instance, and its derivative equation for "rough computations," as the author designates it, are of a similar statical consistency.

Equation 3 has been worked out to enable the finding, according to the author, of the position of the neutral axis.

It is not clear to the writer, however, why the author gives a rather long equation (which, by the way, is not correct), when there are already several plain methods of finding that axis in a reinforced concrete beam.

The writer thinks it would be necessary for the author to devote a few words in justification of his point of view concerning Equation 3.

The writer, in closing, would like to ask the author the reason for his statement that "The unit stress, v, acts parallel to $N\ N'$". The writer has the impression that this statement, as put by the author, is not another of his assumptions, but a true and proper theorem concerning the equilibrium of internal forces in a wedge-shaped beam; and, as such, he would like further explanation. Mr. Janni.

Mr. Mensch.

L. J. MENSCH, M. AM. SOC. C. E. (by letter).—In the discussion of a paper on reinforced concrete construction before this Society several years ago, the statement was made that the counterforts of retaining walls do not act as beams. This alone would show that Mr. Cain's paper is important. It also seems that the writers of textbooks have neglected to devolop theories of wedge-shaped beams, although quite a number of such books contain theories nearly identical with that of Mr. Cain, for curved beams such as crane hooks, arched girders, etc.

Mr. Cain points out that an engineer is apt to overlook the fact that the compressive forces must be multiplied by $\cos.^2\beta$ when entered in the elastic equation, instead of by $\cos.\beta$ which one would be likely to do without going deeper into the matter. Probably a great many mistakes are made on this line, yet it is strange that they are made for the compression side of the beam, though on the tension side it is quite natural to multiply the actual cross-section (which is the $\cos.\beta$ value of the section made by the plane, $I\ N$) by $j\ d\ \cos.\beta$ to find the moment of the tensile forces.

For compression members, in trusses with inclined members, engineers are also accustomed to consider only the cross-section at right angles to the direction of the stress; therefore, it appears to the writer that only carelessness or incompetence is the cause of the mistake complained of. Mr. Cain's theory stands and falls with the fact that plane sections remain plane after deformation.

His assumption that the compressive forces are parallel to the compression face is certainly permissible in all cases where the percentage of reinforcement is low, say, less than 1%, and errs only slightly on the side of danger.

The law or assumption of plane sections remaining plane after deformation is certainly one of the greatest inventions of modern engineering, and enabled us to obtain a great number of simple working formulas, where formerly rules of thumb were used, yet the law is not universal, and is strictly proven only for straight beams of high-grade iron of rectangular section, within the elastic limit, and never for the neighborhood of ultimate load.

Professor Schule, of Zürich, about 12 years ago, proved that this assumption does not hold good for reinforced concrete beams, even under light loads, and why engineers all over the world have utterly disregarded these important tests is certainly strange.

Mr. Mensch.

It is a well-known fact that the plane-section theory for plain concrete beams gives results which vary just 100% from actual tests, and still the same theory is applied to reinforced concrete beams. R. L. Humphrey, M. Am. Soc. C. E., in the discussion of his painstaking tests of 343 reinforced concrete beams, declares that the compressive stresses in the concrete and the tensile stresses in the reinforcement often differed 50% from the theory. In the face of such facts it may be expected that Mr. Cain's table will differ just as much from facts, although it is much better than relying on a mere guess.

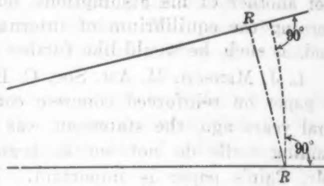

FIG. 11.

Tests of cast-iron beams prove that such wedge-shaped beams fail on a curved surface which is tangent to perpendicular lines to both faces of the beams, as shown in Fig. 11. For this reason the writer has advised* calculating such a counterfort for a section, *R R*, like a common beam, which greatly simplifies the computations and errs on the safe side. Engineers are accustomed to making a similar assumption in case of concrete arches, when they determine the stresses in a section at right angle to the center line of the arch. In view of this fact, it would be well to calculate the fillet in Fig. 4 along a line about bisecting the angle, *N′ N I*, which will be found the dangerous section.

Mr. Nishkian.

L. H. NISHKIAN, ASSOC. M. AM. SOC. C. E. (by letter).—On page 761 the author computes the shear in section *N I*, Fig. 4. An important function of the inclined bar is to relieve the shearing stresses in section *N I*, but the author does not take into consideration the vertical component of the stress in the inclined bar. In order to have equilibrium of all the vertical forces acting on that portion of the base to the right section *N I*, the vertical component of the stress at section *N I* in the inclined bar should be deducted from the total vertical load, 18 333 lb., and the remainder will be the shear in the concrete in section *N I*.

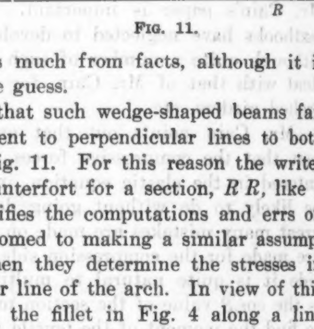

FIG. 12.

* "The Reinforced Concrete Pocket Book."

The sum of the vertical components, per foot of width of the stresses in the inclined bar, is Mr. Nishkian.

$$17\,750 \times 0.765 \times \frac{3}{2} \times \sin.\ 43°\ 10' = 14\,000 \text{ lb.}$$

and $$18\,333 - 14\,000 = 4\,333 \text{ lb.}$$

Therefore the maximum shear in section $N\,I$ is $47.6 \times \dfrac{4\,333}{18\,333} = 11.2$ lb. per sq. in. instead of 47.6 lb. per sq. in.

WILLIAM CAIN, M. AM. SOC. C. E. (by letter).—The writer would like to make a correction as to the meaning of v in Formulas (17) and (18), as others besides Mr. Janni may inquire the reason for the statement that "The unit stress, v, acts parallel to $N\ N'$". The statement is incorrect; v, in Formulas (17) and (18), is the unit shear on any plane, lying between O and the steel bars, perpendicular to $N\ I$. Mr. Cain.

Thus, suppose such a plane drawn in Fig. 8 and marked $A\ A'$ (A lying in $N\ I$, A' in $N'\ I'$), then since the section, $N\ I$, was taken parallel to the direction of the loads, at a point, A, where the bending stress is supposed to be zero, there is shear only on the plane, $N\ I$, and consequently a shear of equal intensity, v, on a plane, $A\ A'$, at right angles to $I\ N$, by a well-known theorem. The total shear on the plane, $A\ A' = v\ b\ dx$.

For equilibrium, the algebraic sum of the components perpendicular to $I\ N$, of the forces acting on $N\ A\ A'\ N'$ must be zero. Therefore

$$(C' - C)\cos.\beta = v\ b\ dx,$$

which is the same as the equation just above (17). Hence, substituting this value in the equation derived just before the last, or in,

$$(C' - C)\cos.\beta\ D\ G = V'\ dx,$$

dividing by dx and then taking the limit, as dx approaches zero and V' approaches V indefinitely, it is found that,

$$v = \frac{V}{b\ D\ G}$$

just as given in Formula (17).

Thus Formulas (17) and (18) are unchanged in form, but v is now to be interpreted to mean the unit shear on a plane perpendicular to $N\ I$, lying between the neutral axis and the steel.

This is the maximum shear, being greater than the shear on any other plane than $A\ A'$ passing through A; hence it is of special interest to the designer.

Mr. Janni makes a perplexing statement when he says: "cos. $(\alpha + \beta)$ is purely a symbol of a certain operation to be performed, and is not an actual value; its value is given by cos. α cos. β — sin. α sin. β." Perhaps this is a "*lapsus calami*". All our textbooks state that the cosine of any angle, as $(\alpha + \beta)$, is an actual value, and gives tables of the actual

Mr. Cain. values for various values of $(\alpha + \beta)$. Also, such values are often represented by certain lines on a unit circle, by aid of which the formula quoted is derived. By a consideration of such line values, it is at once seen that cos. $(\alpha + \beta)$ approaches indefinitely cos. β as α tends indefinitely toward zero, and the same result follows from using the development of cos. $(\alpha + \beta)$.

In fact, take the equation,

$$P\,Q = \frac{v\,\alpha}{\cos.\,\beta - \alpha \sin.\,\beta},$$

which Mr. Janni gives. As he knows, α sin. β is an infinitesimal, and can be neglected in comparison with the finite quantity, cos. β, when connected with it with either a plus or minus sign. Thus, as α tends toward zero, without ever becoming zero, the value of $P\,Q$ approaches $\frac{v\,\alpha}{\cos.\,\beta} = v\,\alpha$ sec. β, which is exactly the formula derived by the writer.

The writer cannot agree with Mr. Janni that the direction of the bending stress on the section, $N\ I$, varies in the manner shown in Fig. 9. It will presently be proved that the stress on the cross-section of an actual beam varies continuously in amount and direction, so that no sudden change in direction of 90° at any point can occur.

This is true even at points of contact of wheel loads, for such loads are in reality distributed. So far as dams are concerned, the changes in the amount and direction of the principal stresses along horizontal sections have been determined, both theoretically and experimentally.

Reference has been made to the experiments on india rubber model dams by Messrs. Wilson and Gore. Fig. 13 is taken from their paper,* giving an account of these very interesting experiments. The unit stresses, in amount and direction, at numerous points in the dam, were determined from the distortions, and are represented by the ellipses of stress shown in the figure. The principal stresses, or those acting normally to their planes, are represented, in amount and direction, by the semi-axes of the ellipses. Of these, the maximum normal stresses are given by the semi-major axes and are those that specially interest us.

It will be observed that along any horizontal section, these unit principal stresses change gradually, in amount and direction. They are also observed to act parallel to the inclined down-stream face, very near that face. At the up-stream face, where the dam is subjected to water pressure, the direction of the principal stress is nearly normal to that face, to counteract the large normal pressure of the water.

The same general results were first found theoretically by Mr. Ernest Prescot Hill,† for a dam with the up-stream face vertical, and later

* *Minutes of Proceedings*, Inst. C. E., Vol. CLXXII, Session 1907-08, Part II.

† In a paper on "Stresses in Masonry Dams," *Minutes of Proceedings*, Inst. C. E., Vol. CLXXII, p. 134.

by the writer* for the up-stream face battered; both writers adopting the usual approximate trapezoid law for the distribution of the vertical components of stress on a horizontal section. Mr. Cain.

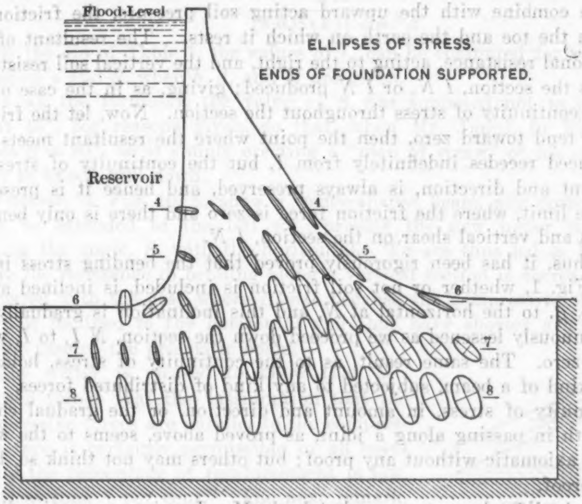

FIG. 13.

Fig. 14 represents the changes in direction of the greater principal stresses, as computed by the writer on a horizontal section of a dam, 200 ft. below the water level, the reservoir being full. For reservoir empty, the principal stress at the up-stream face would act parallel to that face.

Now, suppose that, for a dam of the same size and shape, but of less specific gravity, and capable of exerting tension, the resultant on the horizontal section passes much nearer the outer toe or beyond it; then a part of the section would be in tension, but the theory quoted shows that the continuity of stress, in amount and direction, would be preserved, and that there would be no abrupt changes in either, in going from the up-stream to the down-stream face. This continuity is preserved, as the center of pressure on the base moves indefinitely beyond the outer toe, and hence it is true at the limit, when the weight of the

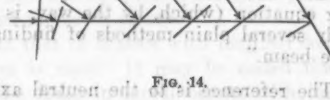

FIG. 14.

* *Transactions*, Am. Soc. C. E., Vol. LXIV, p. 208.

Mr. Cain. dam is neglected and the horizontal section is subjected to a pure bending stress and shear, due to the water pressure alone. Exactly the same reasoning applies to the toe, Fig. 1, supposed to be homogeneous, if we combine with the upward acting soil pressure, the friction between the toe and the earth on which it rests. The resultant of this frictional resistance, acting to the right, and the vertical soil resistance, meets the section, *I N*, or *I N* produced; giving, as in the case of the dam, continuity of stress throughout the section. Now, let the friction force tend toward zero, then the point where the resultant meets *I N* produced recedes indefinitely from *I*, but the continuity of stress, in amount and direction, is always preserved, and hence it is preserved at the limit, where the friction force is zero and there is only bending stress and vertical shear on the section, *I N*.

Thus, it has been rigorously proved that the bending stress in the toe, Fig. 1, whether or not soil friction is included, is inclined at the angle, β, to the horizontal at *N*, and this inclination is gradually and continuously lessened as we proceed down the section, *N I*, to *I*, where it is zero. The same result, as to the continuity of stress, holds for any kind of a beam, subjected to any kind of distributed forces. This continuity of stress, in amount and direction, or the gradual change in both in passing along a joint, as proved above, seems to the writer to be axiomatic without any proof; but others may not think so, hence the proof.

It is difficult to see on what basis Mr. Janni assumes the discontinuity of 90° in the direction of the stress in Fig. 9. Presumably, the stresses act in the direction of the dotted lines. An obvious remark is, that if such directions were the true ones, then the arms of the corresponding stresses are less than those corresponding to the writer's hypothesis; so that even the writer's formulas would be on the danger side for the distribution of stress shown in Fig. 9; and the ordinary formulas, which Mr. Janni advocates, would be still farther on the danger side. There is thus an inconsistency which is fatal to Mr. Janni's contention.

The writer is satisfied that Mr. Janni has not read carefully the derivations of his equations or he would not have stated with reference to Equation 3:

"It is not clear to the writer, however, why the author gives a rather long equation (which, by the way, is not correct), when there are already several plain methods of finding that axis in a reinforced concrete beam."

The reference is to the neutral axis. It is hardly necessary to remark that if the "plain methods" are those pertaining to a prismatic beam (the only case ordinarily treated), they are entirely inapplicable to a wedge-shaped beam.

From overlooking this fact, Mr. Janni's Equation 23 is in error when β is not zero. The correct formula, assuming parallel compressive stresses, is given by Equation 15. Mr. Cain.

$$f_c = \frac{2\,M}{(b\,d)^2\,(k\,j)\,\cos.^2\beta}$$

By the aid of Table 1, the values of f_c can be computed for various values of p and β, when b, d, and M are given.

In all the formulas, the value of β was supposed not to exceed about 45°, for reasons given, so that, when Mr. Janni, in Fig. 10, makes $\beta = 90°$, he is simply erecting a "man of straw" of his own in order to knock him down.

Further, in Fig. 10, to show a wedge-shaped beam, any dotted line must be extended to the left to represent the new upper surface, making the angle, β, with the horizontal. We are thus led to Fig. 1, where the resistance to bending along a vertical section is decreased, as compared with the case where $\beta = 0$, because the compressive stresses are now inclined to the horizontal and thus have shorter arms than for the case of the prismatic beam.

The writer is pleased to know that Mr. Mensch thinks that the "assumption that the compressive forces are parallel to the compression face is certainly permissible in all cases where the percentage of reinforcement is low, say, less than 1 per cent." The next remark, that it "errs only slightly on the side of danger", presumably refers to the hypothesis of conservation of plane sections being adopted, as in the usual theory. Some experiments of A. N. Talbot, M. Am. Soc. C. E., seem to substantiate the hypothesis, those of Professor Schüle going the other way. For working loads, the hypothesis is universally used, as it is found to give safe results for reinforced prismatic beams, hence its adoption by the writer for the wedge-shaped beam, with the distinct proviso, however, that it was not to be used for large values of β.

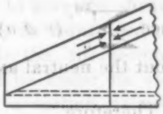

FIG. 15.

Not only on this account, but principally because it was thought that the hypothesis of the compressive stresses, all acting parallel to the face in compression, departed too much from the truth for large angles, β was limited to about 45°, though, possibly, the limit might be extended to $\beta = 60°$, if the results are tempered with good judgment, which means a slightly increased factor of safety.

Mr. Mensch refers to the fact that in trusses with inclined compression members, the right section is used. It may be added that the stresses are taken parallel to the faces in metal beams with inclined flanges. Suppose a reinforced concrete T-beam, Fig. 15, with an inclined flange; would not a designer naturally take the compressive stresses in the flange as acting parallel to its surface? It seems absurd

Mr. Cain. to take them as horizontal, particularly for the part of the flange on each side of the stem.

It is but one step now to the beam, Fig. 1, without a flange.

Mr. Mensch alludes to the fact that errors are sometimes made by using the factor, cos. β, in place of cos.^{2} β, in finding the compressive stresses. To emphasize this point, it should be remembered that A represents the area of a steel bar, taken at right angles to its axis, so that if f_s is the unit stress, the total stress in the bar is $f_s\ A$; but, considering a cylindrical "fiber" of the concrete, $N\ N'$, Fig. 2, the area of its section made by the plane, $I\ N$, is called Δa, so that the area of a section at right angles to the axis of the fiber is (Δa cos. β), and the stress on the fiber is thus, $f_c\ .\ \Delta\ \alpha$ cos. β, f_c being the unit stress on the normal section.

For the fiber, $P\ P'$, Fig. 2, the stress is, similarly, $\frac{f_c}{kd_1}\ v\ .\ \Delta\ a$ cos. β, where $O\ P = v$, and the sum of such stresses over the area, $O\ N$, is,

$$C = \frac{f_c}{kd_1} \cos.\ \beta \sum_0^{kd_1} (v\ \Delta\ a) = \frac{f_c}{kd_1} \cos.\ \beta\ \frac{1}{2}\ b\ (kd_1)^2,$$

since $\sum_0^{kd_1} (v\ \Delta\ a)$ is the statical moment of the area under compression about the neutral axis.

Therefore $$C = \frac{1}{2}\ f_c\ b\ .\ kd_1 \cos.\ \beta,$$

and the moment of C about G is,

$$M_c = \frac{1}{2}\ f_c\ b\ .\ k d_1 \cos.^2 \beta\ .\ D\ G \qquad (8)$$

For the special case given by Fig. 7, G coincides with I, and $D\ G = jd$, on putting $d_1 = d$. Therefore,

$$M_c = \frac{1}{2}\ f_c\ (kj)\ bd^2 \cos.^2 \beta = \frac{1}{2} f_c\ (kj) b\ p'^2,$$

where $p' = d$ cos. β = the perpendicular from I on $N\ N'$ produced.

Mr. Mensch states that he has advised calculating a wedge-shaped beam, Fig. 11, for a section, $R\ R$. It is not clear exactly what Mr. Mensch means by the statement, for there are mathematical difficulties in the way where the section, $R\ R$, is not parallel to the line of action of the loads. However, accepting the hypothesis of parallel compressive stresses, the last equation gives the precise result,

$$M_d = \frac{1}{2} f_e\ (kj)\ b\ .\ \overline{R\ R}^2$$

as $p' = R\ R$, of Fig. 11.

It is to be observed, however, that k and $j = 1 - \frac{1}{3} k$, must be determined for a section (say a vertical section in Fig. 11) through the lower R, parallel to the loads and not for the section, R R, as follows from the derivation of the formula. Mr. Cain.

Formula 16 is in the simplest possible form, and by aid of Fig. 6, the values of k can be read nearly to thousandths and the computation easily effected. As a matter of fact, the steel percentage for the toes, heels, or counterforts of retaining walls, is nearly always very low, so that the steel is the determining factor. In any case, both M_s and M_c should be computed from Equations 14 and 16, for assumed values of f_s and f_c, and the least of the two equated to M, the moment of the external forces; or, if possible, the steel section should be revised, because under-reinforcement is in most cases preferable to over-reinforcement, as it leads to a more progressive, and not a sudden, failure, in case of excess loading.

Mr. Nishkian raises an interesting point in connection with Fig. 4 (referring to the case of the heel-slab with the fillet), that the vertical component of the stress in the inclined rods, for the width, b, should be subtracted from the total external shear to give the shear in the concrete in section, I N. It may be observed, in reinforced concrete beams, that the bending of the beam entails the interaction of steel and concrete, without which the steel would be under no stress whatever. Thus the tensile stress in any bar, at a section, is necessarily accompanied with a reaction or an equal bond shearing stress in the concrete, along the entire surface of contact of the bar, to one side of the section. The steel elongates under stress, and this elongation is resisted by the concrete and the total reaction, for the length of bar to one side of the section—the total bond stress—is exactly equal to the tension in the bar. Thus the stress in the bar does not relieve the concrete of shear directly. Even where there are hair cracks on the tensile side of the beam, the full bond stress is exerted between the cracks, giving rise to ordinary shears, and these in turn to indirect tensions and compressions in the parts intact, which play an indispensable rôle in transmitting stresses and maintaining the integrity of the beam.

To deduce a formula for shear, only a part of the beam, such as is represented in Fig. 8, is considered. In an actual beam, as repeatedly pointed out, the compressive stresses are not all parallel to the face in compression, but their inclinations to the normal to I N become less as the neutral axis is approached. In Fig. 8, the hypothesis of parallel compressive stresses is only used to establish approximately the point, D, the point where the resultant, C, of the compressive stresses cuts I N. If C is now thought of as the resultant of the actual compressive stresses, having varying inclinations to I N, and calling β' its inclination to the normal to I N, the formulas which lead to Equation 17 are unchanged,

Mr. Cain. provided we substitute β' for β. The angle does not appear in the final result. To realize further the conditions in an actual beam, tensile stresses in the concrete must be supposed between the neutral axis and the point where the hair cracks are experienced. Although, in the ordinary theory, such tensile stresses are ignored, yet it is seen, because they actually exist, that the section for maximum shear should strictly be taken at O, or at the neutral axis. Such ignored tensile stresses, though small, are nevertheless effective in changing the directions of the stresses in the concrete between the neutral axis and the point where cracks appear.

Formula 17 can be deduced in a different way from that given, which will introduce that interaction between the steel and concrete first alluded to. Let it be assumed that only shear of intensity, v, is exerted on a plane just below O, Fig. 8, that is, perpendicular to $I\ N$. Hence, adopting the previous notation pertaining to Fig. 8, the total shear on the plane is $v\ .\ b\ .\ dx$.

The bond stress exerted at the surface of contact of any bar, as $I\ I'$, throughout the length, $I\ I'$, is equal to the difference in the tensile stresses in the bar at I and I', and it acts in the direction, $I'\ I$. Hence the total bond stress exerted by all the bars is $(T' - T)$ in amount, and it acts in the opposite direction to T', if $T' > T$.

If we call β_0 the angle made by the resultant, T (or T'), with the normal to $I\ N$, then $(T' - T) \cos. \beta_0 =$ the horizontal component of the total bond shearing stress exerted by all the bars, and this must equal the shearing stress, $v\ .\ b\ .\ dx$, exerted on the plane perpendicular to $I\ N$, just below O. Therefore,

$$v\ .\ b\ .\ dx = (T' - T) \cos. \beta_0.$$

Next, considering the free body, $N\ I\ I'\ N'$, held in equilibrium by the forces, V, V', C, C', T, T', acting as shown in Fig. 8, and taking moments about D,

$$(T' - T) \cos. \beta_0\ .\ \overline{D\ G} = V'\ .\ dx.$$

Eliminating $(T' - T) \cos. \beta_0$ between these two equations, dividing by dx, taking the limit as dx tends toward zero and V' tends toward V, and solving for v, we derive,

$$v = \frac{V}{b\ .\ \overline{D\ G}},$$

or Equation 17, which was first derived by a slightly different method.

At first sight, it might appear that the plane just below O, on which there is only shear, should be parallel to $T\ T'$, so that the shear on it should exactly equal the bond stress $(T' - T)$, which must be transmitted by ordinary shear to the neutral axis; but when we consider that along $O\ S$ (by the hypothesis), there is no bending stress, and

hence no component of bending stress normal to $O\ S$, it follows that there can be only shear on $O\ S$, and hence a shear only of equal intensity on a plane normal to $I\ N$, say just below O, or between the neutral axis and the steel, if we ignore all tensile stresses in the concrete. The first equation above is thus justified. In the final equation for v, the whole external shear, V, appears, and there seems to be no justification for diminishing it by the component parallel to $I\ N$ of the pull in the rods. Mr. Cain.

Paper No. 1296

A STUDY OF ECONOMIC CONDUIT LOCATION.

By C. E. Hickok, Assoc. M. Am. Soc. C. E.

With Discussion by Messrs. H. Hawgood, M. F. Stein, and C. E. Hickok.

The paper entitled "Economic Canal Location in Uniform Countries,"* by Lyman E. Bishop, Assoc. M. Am. Soc. C. E., contains a series of interesting and useful diagrams, by the use of which the locating engineer can quickly determine the economic center line cut for any particular canal section for any slope of ground. However, every conduit, unless it is in a country of uniform topography, must change at certain points from one type of construction to another, in order to be built economically and safely. It is rarely that a conduit of any considerable length can consist entirely of canal section, but rather it must change to flumes, siphons, pipes, bridge flumes, or tunnels, as the conditions demand. The points of change are determined, not only by the slope of the ground, the nature of the material encountered, and certain local conditions, but by economic considerations as well.

In making conduit locations, from time to time, the writer has evolved a diagram, giving the equivalent lengths, from an economic standpoint, of various types of conduit, which has been of considerable value. For instance, when the locator comes to a point where he must decide whether to tunnel through a ridge or follow the grade around with a canal, he measures the length of the two possible routes, and, by an inspection of the diagram, comes to a ready decision. This not only eliminates considerable loss of time, but, if the diagram has been properly constructed, assures a proper and complete comparison between

* *Transactions*, Am. Soc. C. E., Vol. LXXIV, p. 179.

the two alternatives as to first cost, depreciation, head-loss values, evaporation and seepage loss values, interest, taxes, inspection, and repairs.

For purposes of illustration assume a case where the project under consideration is to be used for irrigation and hydro-electric purposes, and where the conduit has a capacity of 44.6 cu. ft. per sec. and a slope of one-tenth of 1 per cent. Four types of conduit are shown in Fig. 1.

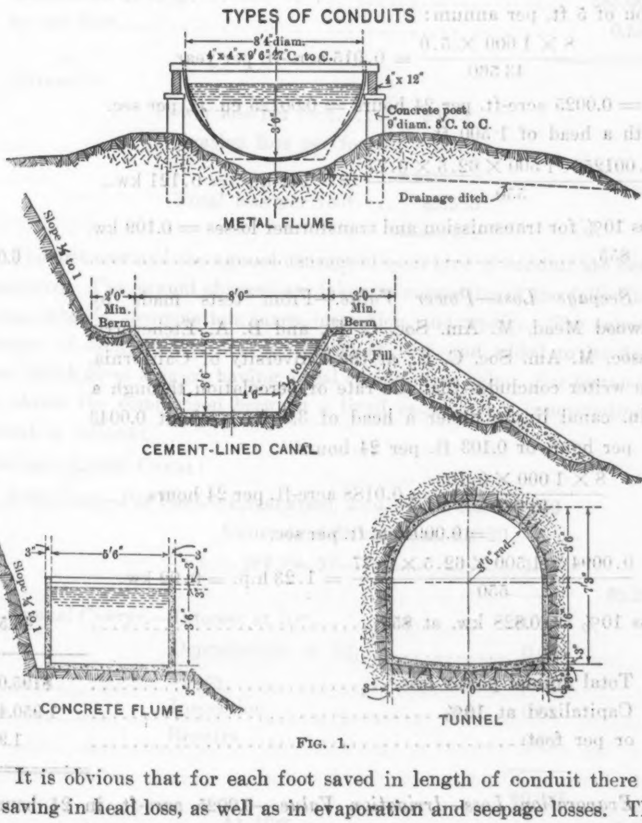

FIG. 1.

It is obvious that for each foot saved in length of conduit there is a saving in head loss, as well as in evaporation and seepage losses. The value of this saving is ascertained in the following way, taking 1 000 ft. of conduit, for convenience in calculating:

Head Loss.—1 000 ft. of conduit dissipates 1 ft. head. With a discharge of 44.6 cu. ft. per sec., and 77% efficiency, the horse-power is

$$\frac{1 \times 44.6 \times 62.5 \times 0.77}{550} = 3.9 \text{ h.p.} = 2.8 \text{ kw.},$$

less 10% for transmission and transformer losses = 2.61 kw. at \$55 .... \$143.50

Evaporation Loss—Power Value.—Assuming an evaporation of 5 ft. per annum:

$$\frac{8 \times 1\,000 \times 5.0}{43\,560} = 0.915 \text{ acre-ft. per year}$$

$= 0.0025$ acre-ft. per 24 hours $= 0.00125$ cu. ft. per sec. with a head of 1 500 ft.,

$$\frac{0.00125 \times 1\,500 \times 62.5 \times 0.77}{550} = 0.162 \text{ h.p.} = 0.121 \text{ kw.},$$

less 10% for transmission and transformer losses = 0.109 kw. at \$55 .... 6.00

Seepage Loss—Power Value.—From tests made by Elwood Mead, M. Am. Soc. C. E., and B. A. Etcheverry, Assoc. M. Am. Soc. C. E., at the University of California, the writer concludes that the rate of percolation through a 3-in. canal lining under a head of 3.5 ft. is about 0.0043 ft. per hour, or 0.103 ft. per 24 hours.

$$\frac{8 \times 1\,000 \times 0.103}{43\,560} = 0.0188 \text{ acre-ft. per 24 hours}$$

$$= 0.0094 \text{ cu. ft. per sec.}$$

$$\frac{0.0094 \times 1\,500 \times 62.5 \times 0.77}{550} = 1.23 \text{ h.p.} = 0.92 \text{ kw.}$$

less 10% = 0.828 kw. at \$55 .... 45.54

Total annual power loss	\$195.04
Capitalized at 10%	1 950.40
or per foot	1.95

Evaporation Loss—Irrigation Value.—0.0025 acre-ft. in 24 hours (from the foregoing) = 0.00125 cu. ft. per sec. = 0.0625 miner's inch. Assume 25% loss before delivery to consumer:

0.047 miner's inch at \$0.40 per miner's inch per day = per annum \$6.86

Seepage Loss—Irrigation Value.—0.0188 acre-ft. per 24 hours (from the foregoing) = 0.0094 cu. ft. per sec. = 0.47 miner's inch, less 25% loss = 0.353 miner's inch at \$0.40 per miner's inch per day = per annum 51.64

Total annual irrigation loss	\$58.50
Capitalized at 10%	585.00
or per foot	0.585

Résumé.—

Power loss per foot	\$1.95
Irrigation loss per foot	0.585
Total loss per foot	\$2.535

The first cost and the annual charges of each type of conduit are next computed. The annual charges are taken as consisting of the following items: interest, depreciation, taxes, inspection, and repairs. The annual charges of each conduit are capitalized at 10% and added to its first cost, which gives a figure having a real comparative value. For instance, we obtain the comparison between a lined canal and a concrete-lined tunnel as follows:

CONCRETE-LINED CANAL:

First Cost—Per Foot.—	Excavation, 2 cu. yd. at \$0.36	\$0.72	
	Concrete, 4.25 cu. ft. at \$10.20 per cu. yd.	1.57	
			\$2.29
Annual Charge.—	Interest at 10%	\$0.23	
	Depreciation at 2%	0.046	
	Taxes	0.019	
	Inspection	0.01	
	Repairs	0.02	
		\$0.325	
	At 10%		3.25
			\$5.54

CONCRETE-LINED TUNNEL:

Excavation, 2.25 cu. yd. at $5.50	$12.40	
Concrete and forms	4.10	
		$16.50

Annual Charge.—Interest at 10%	$1.65		
Depreciation at 1%	0.165		
Taxes	0.137		
Inspection	0.01		
Repairs	0.02		
		$1.982	
At 10%			19.82
			$36.32

It is evident, if we shorten the conduit by building the tunnel, that the first cost and the capitalized annual cost of the tunnel can exceed the first cost and the capitalized annual cost of the canal by an amount equal to the length of conduit saved multiplied by the loss value per foot of conduit. This is shown by the equation:

$$Y\ (C_y + A_y) = X\ (C_x + A_x) + (x - y)\ V$$

where X = linear feet of canal,
Y = linear feet of tunnel,
C_x = estimated cost per foot of canal,
A_x = estimated annual charges per foot of canal capitalized at 10%,
C_y = estimated cost per foot of tunnel,
A_y = estimated annual charges per foot of tunnel capitalized at 10%,
and V = value of losses per foot of conduit.

In the case of a tunnel, the evaporation will be considerably lessened, thereby effecting an additional saving. If entirely eliminated, this saving would amount to 12.8 cents per ft., as shown above. This was reduced to 10 cents and the first cost of tunnel credited with that amount. Inserting the proper values in the equation:

$$Y\ (16.40 + 19.82) = X\ (2.29 + 3.25) + (x - y)\ 2.53$$

$$Y = 0.208\ X, \text{ the equation of a straight line.}$$

In the same way, any two types of conduit can be compared and the resulting straight-line equation obtained. The diagram, Fig. 2, which is self-explanatory, shows the results.

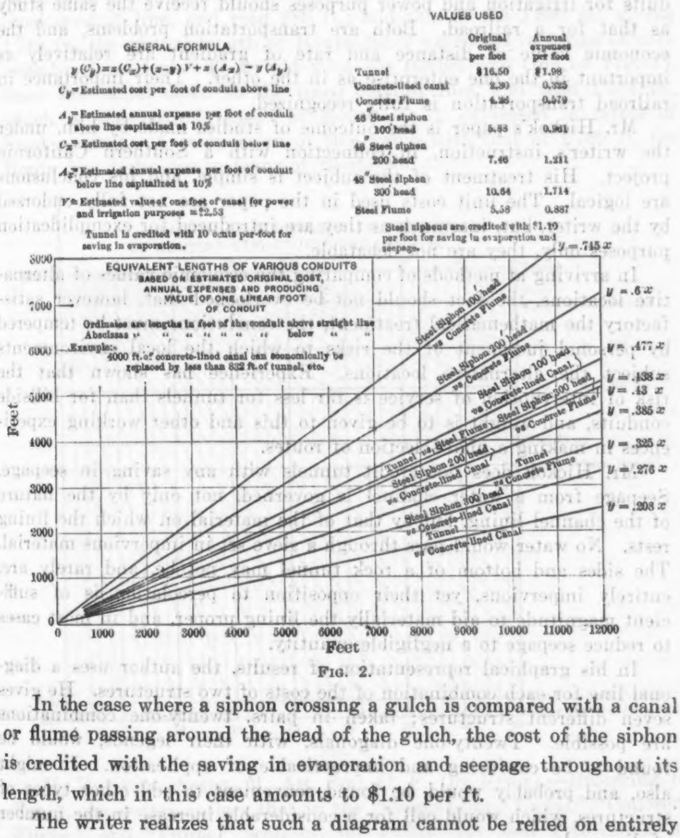

FIG. 2.

In the case where a siphon crossing a gulch is compared with a canal or flume passing around the head of the gulch, the cost of the siphon is credited with the saving in evaporation and seepage throughout its length, which in this case amounts to $1.10 per ft.

The writer realizes that such a diagram cannot be relied on entirely in the location of a conduit, for there are local conditions on every piece of work which must be taken into account.

DISCUSSION

Mr. Hawgood.

H. Hawgood, M. Am. Soc. C. E. (by letter).—The location of conduits for irrigation and power purposes should receive the same study as that for a railroad. Both are transportation problems, and the economic value of distance and rate of gradient are relatively as important in the one enterprise as in the other. Their importance in railroad transportation is fully recognized.

Mr. Hickok's paper is the outcome of studies made by him, under the writer's instruction, in connection with a Southern California project. His treatment of the subject is simple, and his conclusions are logical. The unit costs used in the paper are not fully endorsed by the writer, but, inasmuch as they are introduced for exemplification purposes only, they are not debatable.

In arriving at methods of comparing the economic values of alternative locations, the fact should not be overlooked that, however satisfactory the mathematical treatment, the conclusions must be tempered by personal judgment of the risks to which the local environments subject the alternative locations. Experience has shown that the risk of interruption of service is far less for tunnels than for hillside conduits, and weight is to be given to this and other working experiences in making a final selection of routes.

Mr. Hickok does not credit tunnels with any saving in seepage. Seepage from a water channel is governed, not only by the nature of the channel lining, but by that of the material on which the lining rests. No water would pass through a sieve set in impervious material. The sides and bottom of a rock tunnel may not be, and rarely are, entirely impervious, yet their opposition to percolation is of sufficient magnitude to aid materially the lining proper, and in most cases to reduce seepage to a negligible quantity.

In his graphical representation of results, the author uses a diagonal line for each combination of the costs of two structures. He gives seven different structures; taken in pairs, twenty-one combinations are possible. Twenty-one diagonals, with their legends, would be found to be confusing and impracticable of application. It might also, and probably would, be found convenient to add other types of structures, which would call for a considerable increase in the number of diagonals.

The writer suggests Fig. 3 as a more convenient form of diagram and as covering all phases of the subject. The radiating lines permit finding the equivalent distance, or type of structure, in terms of length of any other type of structure. The horizontal lines, each representing a particular type of structure, are spaced so that their distances apart vertically bear the same ratio one to the other as their respective unit costs. To exemplify the use of the diagram, assume that, of two

alternative routes, Route No. 1 has 200 ft. more tunnel and Route No. 2 has 1 500 ft. more lined conduit and 300 ft. greater length of line. Find Vertical 3 on the base line representing the economic value of 1 ft. of distance; trace the radial thence up to the concrete-lined conduit line, and read 289 ft.; add this to the 1 500 ft., giving 1 789 ft., the virtual length of Route No. 2 expressed in terms of concrete-lined conduit. Then find 2 on the tunnel line (top of Fig. 3), trace the radial down to the lined conduit line, and read 1 324 ft., which is the virtual length of Route No. 2 expressed in terms of lined conduit. A comparison of this value with that of 1 789 ft. for Route No. 2, decides in favor of Route No. 1. Mr. Hawgood.

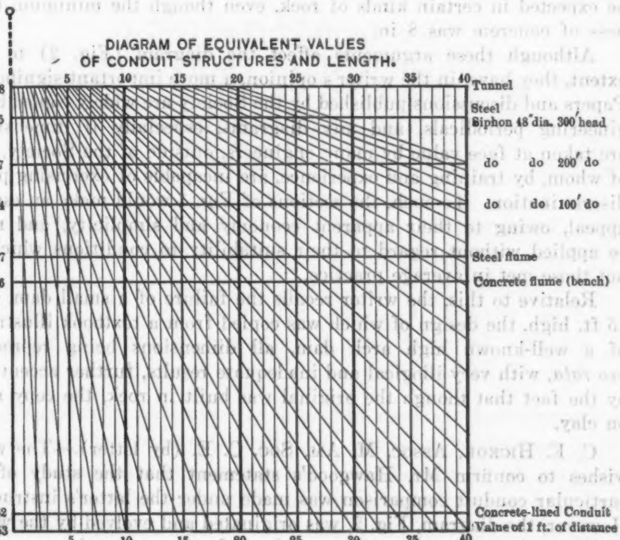

FIG. 3.

M. F. STEIN, ASSOC. M. AM. SOC. C. E. (by letter).—Referring to Fig. 1, the writer notices that in the "Cement-lined Canal," "Concrete Flume," and "Tunnel" sections, the author has used a thickness of concrete of 3 in. It would seem, from the writer's experience and observation, that though this thickness may be theoretically sufficient to withstand the water pressure, it may not give a sufficient factor of safety for various contingencies which cannot be calculated. It is generally difficult to obtain water-tight construction with a thin wall, using the customary type of labor and superintendence in mixing and placing the concrete, and frost action may prove destructive in Mr. Stein.

Mr. Stein.

a cold climate, especially in the event of seepage through the concrete. A thin section, furthermore, provides little safety against cracking, should there be any unequal settlement. These points would apply with less force in a warm and arid region, but the author does not limit his discussion to such conditions.

As regards the tunnel lining, though this may be sufficient for very firm rock, where it is only desirable to obtain a smooth surface, for hydraulic reasons, it would not offer much resistance to the rock movements, shelling, and thrusts experienced in limestone, shale, or clay formations. This is exemplified in the recent failure of the Montreal conduit, under an apparent pressure much less than might be expected in certain kinds of rock, even though the minimum thickness of concrete was 8 in.

Although these arguments affect the diagram (Fig. 2) to some extent, they have, in the writer's opinion, a more important significance. Papers and discussions published by the Society are widely copied by engineering periodicals, and any diagrams, especially if dimensioned, are taken at face value by many engineers, outside of the Society, some of whom, by training and experience, are incapable of exercising proper discrimination. To such, the sections of Fig. 1 would make an especial appeal, owing to their apparent economy and simplicity, and might be applied without regard to their suitability to conditions which are not those met in average practice.

Relative to this, the writer recalls the failure of a small dam, about 15 ft. high, the design of which was copied from a textbook illustration of a well-known high arch dam, all dimensions being reproduced *pro rata,* with very illogical and inadequate results, further accentuated by the fact that though the original was built in rock, the copy rested on clay.

Mr. Hickok.

C. E. Hickok, Assoc. M. Am. Soc. C. E. (by letter).—The writer wishes to confirm Mr. Hawgood's statement that the study of this particular conduit comparison was made under the latter's instruction. However, the diagram, Fig. 2, was originated and evolved by the writer.

The writer did not credit tunnels with any saving in seepage, as he was unable to ascertain even an approximate figure for this saving. He agrees with Mr. Hawgood that there would be a saving, but this depends so much on the nature of the tunnel material, which may vary from a pervious soil to hard rock, that there was a hesitancy as to what value to place thereon. There might even be an addition to the discharge of the conduit in the tunnel due to underground waters.

Mr. Hawgood's diagram, Fig. 3, is interesting and is certainly more compact than that of the writer.

In regard to Mr. Stein's remarks as to the thickness of the concrete in the different types of conduit, it should be stated that these drawings, Fig. 1, were not inserted in the paper to illustrate construction details,

but simply for pictorial purposes. The drawings were not necessary, and possibly should have been omitted. The writer hopes that no engineer would attempt to construct, for instance, a concrete flume similar to that shown on Fig. 1, without reinforcement. In regard to the 3-in. thickness of concrete lining in the tunnel, the section was supposed to be in solid rock, and no concrete lining was intended to be shown above the springing line. This escaped the writer's notice, due to the fact that he was more interested in the real subject than in construction details. Mr. Hickok.

Paper No. 1297

THE DEPRECIATION OF PUBLIC UTILITY PROPERTIES AS AFFECTING THEIR VALUATION AND FAIR RETURN.*

BY JOHN W. ALVORD, M. AM. SOC. C. E.

WITH DISCUSSION BY MESSRS. W. J. WILGUS, J. E. WILLOUGHBY, FRANK C. BOES, ALLEN HAZEN, H. C. VENSANO, LEONARD METCALF, WILLIAM B. JACKSON, F. LAVIS, ALEXANDER C. HUMPHREYS, HENRY FLOY, CLINTON S. BURNS, STUART K. KNOX, J. H. GANDOLFO, CHARLES RUFUS HARTE, W. KIERSTED, GEORGE B. STONE, AND JOHN W. ALVORD.

Depreciation has been discussed so fully since the regulation of public properties has become important, that space will not be taken here to review fundamentals. This discussion is directed to the question of the general relation of depreciation and its effects on the fair return of a utility property, and also, to some extent, to methods of accounting for depreciation in the administration of such properties.

For the general purpose of this paper, it will be considered that the term "depreciation" covers all the losses of value that occur in property, plants, or parts thereof, from wear and tear, obsolescence, or inadequacy. In other words, it will make no difference in this study whether the loss of value arises because the structure is outgrown, becomes obsolete through changes in the art, or is merely worn out. All these various ways by which value is lessened will be classed under the general term, "depreciation".

* Presented at the meeting of December 17th, 1913.

The Reproduction Method of Valuation.—In dealing with depreciation as affecting valuations, it must be clearly borne in mind that we are discussing only that line of evidence as to value known as the reproduction method, or cost new less depreciation. This line of evidence is only one source of information as to value, because plants or properties may or may not be worth what it costs to reproduce them, and no appraisal or valuation is at all complete which relies wholly on reproduction or cost new less depreciation methods. Other lines of evidence are equally important before arriving at value.

The reproduction method, however, is an important line of evidence, and must always be studied; and the relation of depreciation to cost new is therefore vital. This relation is discussed herein.

Depreciation as Affecting the Fixing of Rates.—Recently, the question has been asked, "Should depreciation be deducted from the investment cost of a property before computing fair return?" This question was discussed by C. E. Grunsky, M. Am. Soc. C. E., in his paper entitled "The Appraisal of Public Service Properties as a Basis for the Regulation of Rates."* Mr. Grunsky contends that depreciation should not be deducted for rate-making purposes, but the original investment should be used for the fixing of rates, on the theory that the investment must be maintained intact, first, by the maintenance of the plant, and, second, by a sum set aside for renewals from time to time. The question is also discussed in a paper by Mr. Robert H. Whitten,† of the New York Public Service Commission, who concludes that, for rate-making purposes, the depreciation should be deducted from the reproduction cost. Mr. Samuel S. Wyer,‡ of Columbus, Ohio, expresses the opinion that the cost of reproduction. less accrued depreciation, is not the proper basis for rate-making, but does not make it quite clear whether he means this to apply to cases where the sinking fund for depreciation is in hand or not.

Here, therefore, there seems to be a very serious disagreement, among authors who have written recently on this subject, as to whether or not depreciation should be deducted from the cost new of a property for finding value for rate-making purposes where the reproduction method is adopted as a basis of value. It seems to be desirable, there-

† *Engineering News*, May 8th, 1913.

‡ In his book, published recently, "Regulation, Valuation, and Depreciation of Public Utilities," Chapter 13, p. 185.

fore, to present a further study of this question. Certainly there must be in this, as in all other questions relating to this difficult subject of valuation, a just and equitable relation between the public and the public utility owners, which is founded on rational analysis and common sense.

At the outset, it may be said that the sinking-fund method seems to be an accurate way to compute depreciation where all or most of the life history is known, as it consists largely in finding past depreciation. This is mainly because the sinking fund is without emolument to the owners of the plant, and therefore has in it no element of confusion.

The sinking-fund method of computing or allowing for depreciation consists in determining the proper useful life of the structure or machine under consideration, and setting aside from year to year a sum of money which, with its annual increment of interest, will, at the end of the assumed life, replace the structure or machine in question.

In case a portion of the life has passed away, the present value of such structure or machine is assumed to be, in a general way, the present cost of replacement new, less the accrued amount of the depreciation fund to date.

The sinking-fund method, however, when practically applied to a great variety of structures in a plant of a wide and varied character, is a complicated and difficult way for the accountant to write off depreciation for the future, especially where most of the data must be assumed and where they do not warrant that degree of accuracy that a sinking-fund computation would imply.

It is often found practical, therefore, and rational, to determine past depreciation on the terms of a sinking-fund basis, while future depreciation may be practically set aside on a uniform-increment method for simplification. There seems to be no reason why the two methods cannot be made to correspond, if desired, or why this combination is not as rational, under the circumstances; as the future is quite largely prophecy, in any event.

In dealing with theory, however, it seems best to use the sinking-fund method in illustration, as it appears to be the accurate way in which to think out the governing principles.

Actual versus Theoretical Depreciation Funds.—Let it be clearly understood, first of all, that a sinking fund for depreciation, actually

set aside under suitable trust provisions, is to be considered as a part of the property, and, where it is found intact and of proper amount by the appraiser, it should be thus considered, and no deductions from cost new or reproduction cost, where that method is being used, would be necessary.

Where a proper depreciation fund is not set aside actually, but is only estimated and written off in the accounts, there is no such condition, and the matter of writing it off by the owner in his books amounts to only an opinion of his as to what such depreciation fund should be, but does not at all produce such a fund, or make it available; in consequence of which, an appraiser, using the cost new or reproduction method as one of the means of arriving at the value of the property, and finding no depreciation fund actually in hand or in trust, is obliged to deduct it from the property.

In other words, no amount of accounting or theorizing can make good a depreciation fund which is actually not in hand. A clear perception of this principle will save much confusion of thought.

The Attempt to Simplify the Question.—In order to understand the dilemma which a certain line of thought has been recently attempting to follow in this matter, an effort will be made, first of all, to state the case from such a standpoint.

Probably the most simple proposition which would occur to one first considering this question would be the case where the composite life of an entire plant or property has been estimated; that is to say, where the depreciations of all its component parts have been thoughtfully determined, the probable life of each component part established, its age found, and the amount of a sinking fund which will replace it at the end of its life computed. The average life of these component parts should give the composite life of the plant, at the end of which—theoretically at least—it would be subject to entire renewal; in other words, at that time, supposedly, the original investment would have completely disappeared.

To state more fully this line of thought (which has led to certain perplexities), let it be assumed for the moment that no additions are made to the plant, and that it is the purpose to hold the original investment intact. It is commonly considered in such case that if one computes (but does not set aside) a sinking fund for renewals, its accumulations, year by year, if properly estimated, will represent in a general way the decreasing value of the property, or at least roughly

so. If one deducts this sinking fund each year from the original value, to determine the value on the reproduction basis, and computes the rates which would be necessary in order to pay all charges and a fair return on the same, one would have, theoretically at least, a slowly decreasing valuation, year by year, on which to predicate rates, and the rates themselves would therefore necessarily lessen year by year until at the end of the composite life of the plant, there would properly be no rates at all, and, theoretically at least, the entire investment would be represented in the sinking fund, if there was one.

In California, under the laws which formerly existed for some years, such conditions seemed to be contemplated, for it was expected that plants would be valued, or might be valued, every year, for rate-making purposes. It was the existence of this law that probably led Mr. Grunsky to speculate on this particular problem, and his paper has convinced some students of the subject that the rates should not decrease with the depreciated value of the plant from year to year, but should be predicated on what he calls the "original investment", without deducting depreciation. That this appears plausible on its face, one would not at first be inclined to doubt, but it is believed that closer analysis will show that it is not sound in reasoning.

It should be noted, of course, that a sinking fund itself actually set aside is not a source of revenue to the owner, because its interest accretions are necessary to its own growth and purpose; therefore, it is argued that it may properly receive return outside of its own interest accretions. At the end of the life of a given plant, under this theory, it will be receiving the full rates on the full investment, but with a practically worn-out plant, together with a sinking fund in the bank which will entirely replace it. Theoretically, also, it is argued that, if the owner were to go out of business, he could take the entire fund with him, and consider himself recouped for his property. Of course, he would not be entitled to rates any longer. If it is supposed that he should decide to remain in business, he would immediately have to invest the entire sinking fund again in complete renewals, and receive rates based on the full necessary investment, all of which seems to point superficially to the conclusion that the rates, at all times, should be determined by the value of the undepreciated property.

There is much more to the question, however, than the above simple presentation would seem to indicate.

Perpetual Life.—As a matter of fact, depreciation is not as simple in its practical operation as just stated. In the first place, it is not contended seriously by any one familiar with the subject that a plant usually or normally has a point at which its life actually terminates.

A casual inspection of the life of various structures used by appraisers shows that, in any given plant, a great variety of useful existence is assigned from experience to different structures, so that actually none of the component parts of a plant can be said to terminate at one and the same time, but each part must be renewed independently at such time as the necessity arises. This would result in practically repeated reductions of the depreciation fund, if one actually existed, and the absorption of its funds from time to time into the plant. Therefore, there is no one time at which the depreciation fund actually does or can rise to a very large amount; and it would be practically impossible, under normal conditions, that it should ever grow in amount, even to the larger part of the original investment. As a matter of practical observation, it rarely ever theoretically amounts at any one time to more than from 20 to 25% of the original investment, and more frequently is from 10 to 15%, because, as a matter of practical necessity, renewals must be made and the plant must be maintained and perpetuated, whether the owners would desire it or not. Commonly, therefore, one does not have the condition that the plant is wholly, or even largely, renewed by the depreciation fund at any one time, except under the abnormal circumstances of complete failure through errors in original judgment, or, in rare cases, by reason of duplication or other ignorant lack of conservation.

To illustrate: for instance, in the case of a water-works plant, the boilers, ordinarily, will need to be renewed about once in every 20 years. They would probably be renewed about five times in 100 years, and at the end of about 75 to 150 years the pipe system, theoretically, would be renewed to a considerable extent. The buildings, on the other hand, might be renewed about two and one-half or three times during this average interval, and reservoirs about one and one-half or two times, so that, at the end of 100 years, there might still be a plant of some kind, existing in much the same general

form as the original one, except that those parts which may have become obsolete through changes in the art or method would require that their renewals take other form and character. Therefore, one is dealing practically with a perpetual aggregation of structures, which, not only must be maintained, but must also grow, expand, and enlarge. It is true that in some instances public utility plants have been built, run for a time, and abandoned. This is less and less true as time goes on and such enterprises are better understood. These cases of abandonment are so few as practically to be negligible in reasoning out this matter. The tendency of the times is to conserve and protect such property more and more from destruction or failure.

Utilities Commonly Require Growing Plants.—As a matter of fact, in considering depreciation, the original investment must not only be continued intact by frequent renewals, but, in all ordinary growing cities, must be rapidly increased from time to time by the addition of new capital expended in extensions and enlargements. These new extensions, in turn, have their depreciation, which must be provided for, and they, in turn, must be renewed when their time of usefulness has expired. The actual depreciation, therefore, at any given date in any plant, is the sum of all the depreciations of the various structures then in place, duly considering their age and probable life.

Earning Power of Depreciated Plants.—In considering the matter of the depreciation of a public utility plant, one must not confuse its loss of physical value, as measured by the growth of the depreciation funds, with its ability to have earning power. The progress of a plant in earning power is almost always distinct from its progress in depreciation or appreciation, and though it is generally considered that depreciation of physical property is usually followed by lessened earnings, this is not always true. A plant may not be well maintained, but its earning power may at the same time be well maintained, or even grow rapidly. Theoretically, one may sometimes have the condition (in certain kinds of plants at least), as in the sample illustration used at first, where the depreciation, as measured by the deduction of a sinking fund, becomes greater and greater year by year when plant renewals are not properly made, and where an almost worn out plant may be able to earn much more than the return it earned when new.

Of course, there is a limit to this condition; with certain kinds of plants it is not usually possible; and the sin of too long deferred renewals often brings heavy punishment, yet the fact remains that the earning power of a plant is not always controlled by the defects of depreciation.

Natural Accretions.—A plant or property not only depreciates, but also has sources from which it may appreciate. These appreciations of value have been held to be part of the property, by the Supreme Court of the United States, in the Monongahela Navigation case, and more recently in the case of the Kings County Lighting Company *vs.* The Public Service Commission of New York, First District. One of the reasons the Courts have for favoring the reproduction method, or cost new less depreciation, lies in the fact that such procedure includes appreciation as well as excludes depreciation.

When dealing with the valuation of public utilities, it must be kept clearly in mind that a "property" is being considered, and that property may be defined as being all that can be properly transferred to a buyer. Pipes or conduits laid in crowded streets, where many other conduits and tracks, pavements, and heavy traffic would make it difficult to replace them, certainly have a greater reproduction value than they had originally, when the city was unimproved and the streets were open and free for their installation. Right of way and lands, of course, have natural accretions in value, and this is well recognized and understood by the public. What the public does not understand is that similar accretions in value accrue to the property in other items as well as in the increased value of the land.

The Constitution of the United States, in referring to that which must be protected from confiscation, uses the word "property", and not "investment", and the term "property" must necessarily include all the assets which inevitably inhere to, and can be transferred with, the whole entity used and useful for the public.

There are some increments of value produced in connection with an enterprise which originally entailed considerable investment, but cannot be thus transferred, and therefore do not form permanently a part of the property. For instance, a company may have expended a great deal of time, pains, and money, in its original introduction of light, or water, or transportation, for the education of the public as to the value that arises from the use of these facilities. Where

a whole community has been thus educated, it has acquired a fundamental conviction that a utility is really necessary and useful, which conviction, though perhaps developed largely at the expense of a utility company, cannot be transferred as an asset with its property. This is the reason that, in computing costs of development in a rebuilding estimate, it is usually assumed that the public is now already educated in the use of the facility, and would quickly avail itself of the privileges if such facility were reinstalled.

Sinking Funds an Inherent Part of the Plant.—If money has been invested in property which is to be maintained perpetually, and if the public is to be protected by requiring only a fair return based on reasonable rates for the use of this property, such property must be maintained intact by setting aside, as part of the operating expenses, amounts which will sufficiently renew it in part from time to time. In the Knoxville case, the Supreme Court of the United States has held that this is reasonable and proper. If, therefore, one has the right to set aside this money from time to time, theoretically, one should set aside just so much as will maintain the original property in its original form, or the property plus its additions, accretions, and betterments in their total form. To do this will necessitate having on hand, theoretically, part property and part renewal fund. The renewal fund, therefore, is just as much an inherent part of the property as are the tracks, stacks, or boilers, if the property is to be considered as held intact. Where, therefore, one has to value a plant for sale or transfer, and does not find that a renewal fund has been accumulated, or is actually on hand, it is right and proper that one should, so to speak, "fine" the owners, for the absence of this part of the property, by the amount thereof. If the sinking fund for renewal is in the bank or in trust, as well as accounted for on the books of the company, and inherently a part of the property, and in proper amount, one should, naturally, on the other hand, give to the owners of such property the entire reproduction cost of the property undiminished by any depreciation deduction whatever.

It is clear, therefore, that, as far as valuation for the purpose of sale is concerned, it is right and proper that, in the absence of actual sinking funds or any sufficient reserve fund, they should be deducted from reproduction cost or "cost new", when that method is used to

ascertain value. Does not this also hold good in the case of valuation for rate-making?

The Practical Treatment of Depreciation Accounts.—As a matter of fact, few, if any, administrators of public utilities have ever (as far as known, up to date) actually accumulated a sinking fund. Most companies otherwise invest money which would theoretically go to such a fund, because they have thought that such moneys could usually earn a greater rate of interest than they would in a guaranteed sinking fund, and there is the feeling, also, that there would be no difficulty or hazard in relying on the ability of the owner or owners to replace the sinking fund from outside sources from time to time as demands on it occur. This is especially true where the management is more or less personal, and is perhaps not improper, from the point of view of a stockholder, but it means, however, that at all times the property does have within itself, and accounted for on its books, all the elements of the full original value which it had at the start, and to which it is entitled.

To illustrate this situation further, one may take, as an example, a railway having extra rolling stock which is only needed at certain seasons of the year when the traffic amounts to a maximum. It must be admitted that such rolling stock is inherently a proper part of the property, but if the owners decided they could spare this extra rolling stock and should sell it, and should depend on replacing it promptly by some unusual exertion when it was actually needed in the time of maximum traffic demand, they would be in very much the same position as they are when they rely on their ability to replace the sinking fund for depreciation when it is needed. In other words, a part of the necessary property "used and useful for the public" is not present and is not accounted for; and, on a valuation or sale, or even for rate-making purposes, they would have to produce this property, or suffer the diminution necessary to the value of the property by reason of its absence. To state it in another way: a utility company plant is not as valuable to the public without a reserve fund for replacement as it is with such a fund intact and on hand and promptly available.

Absent Depreciation Funds as Affecting Rate-Making.—When one seeks to determine the fair return, through proper rates, on the property of a public utility, it is necessary, in order to protect the public,

to determine carefully the value of the property on which such fair return will be allowed; and if it is found that the owners of the property think it a reasonable and proper policy at all times to take out of the property some part thereof, which is ultimately and finally necessary for its maintenance and continuation, and use that part in other ways, perhaps for private gain, one is under the necessity of denying that they can logically earn rates on the part that is removed and separated from the property to which it belongs.

If a sinking fund for depreciation is on hand and attached to the property, then, by reason of the fact that it itself is not a productive fund to the owners, they should certainly earn rates on it. If, however, they assume that they can take the necessary risks and earn more money on such funds elsewhere, and withdraw such funds from the plant and property, then they must of necessity face the contingency that they cannot be allowed by the public to earn rates on those moneys, on the one hand, and use them for private and outside gain, on the other.

It may be objected that it is a hardship on owners of public utilities, who are able and willing to replace in the property such portion of the renewal fund at any moment that occasion might demand, that they should be made to place in trust such moneys and be denied the privilege of their use for outside enterprise; but it will be easily seen that to accord them this privilege does not ordinarily work out with fairness to the public. A public utility owner, under such circumstances, is tempted to let his plant run down, and withdraw from the property the funds necessary for its renewal from time to time, and use such funds for his other gainful purposes. He may then sometime sell his plant (less reserve fund), and the new owner is obliged to furnish what he has not previously withdrawn. The new owner will naturally demand that rates be made such as would net him a fair return on the undepreciated property under these circumstances. Obviously, here, an injustice would be done, primarily to the public and to the new purchaser as well. The whole procedure thus amounts to the withdrawal by the original purchaser of an unearned dividend, and this is rendered possible by the fact that most utility properties have appreciation as well as depreciation, so that, practically, it is the natural accretion that is withdrawn in this manner. The only practicable way to prevent public utility owners from adopting this procedure is to require that the reserve funds for

renewal shall be kept intact as part of the plant and the property; or that the owners be properly fined, so to speak, by the amount of the funds removed or withdrawn.

Outside Investment of Depreciation Funds.—A great deal has been said in defence of outside investment of depreciation funds. Obviously, reserve monies can earn a larger rate of interest in many other ways than in guaranteed reserve funds. A guaranteed depreciation fund, especially for long periods, will not be undertaken by bankers or trust companies at more than a 3½ or 4% rate, and for unusually long periods, say 100 years, the rate must be still lower, say 2½ to 3 per cent.

It has been customary with appraisers to recognize this fact in computing sinking funds on a sliding scale, in accordance with the length of life of the structure to be provided for.

Now, these monies that would be thus set aside in sinking funds are susceptible ordinarily of being invested at much higher rates for general purposes, and where a given result at the end of a given time does not have to be guaranteed, for instance, such monies may be invested as new capital in new construction and extensions in the very plant itself to great advantage, commanding there often as high a return as 7 or 8%, with, of course, the general risk incident to the enterprise.

It is believed by most administrators that this is an entirely proper way to manage such funds, but it is obviously subject to the reasonable conclusion that the owner cannot have a return on it as a "sinking fund" for depreciation, even if he carefully accounts it as such, and at the same time have a return on it as a betterment to the plant. This would be an obvious injustice to the public.

It is also obvious that another drawback to this procedure lies in the fact that the owner must be willing and ready to finance the replacements and depreciation fund, whenever the occasion therefor arises, and make good for such needs as arise in the non-existing depreciation fund. His temptation will easily be to defer and delay, under these circumstances, perhaps to the great disadvantage of the plant and the public, and although he usually has ample notice of future requirements in such funds, it often occurs that the reserve funds are suddenly necessary for accident or emergency.

If this practice of outside investment of reserve funds is to be ultimately allowed by the utility commissions, the owner's problem becomes an economic one, and is only solved by a close analysis as to whether a depreciation fund, earning return and guaranteed by low rates of interest, is more profitable to the owner than the use of the monies elsewhere at higher rates of interest, and the resulting loss of return in connection with the plant. It would appear on the face of the problem that, if rates are to include a return on the sinking funds set aside for depreciation, as well as on the depreciated property, it would be more profitable for the owner to maintain the full fund constantly in actual existence, and it is believed that, when this question has been fully understood and discussed, this procedure will be required by the utility commissions.

Present Practice.—The practice, thus far, where reproduction cost is adopted, has been to deduct a theoretical depreciation fund (where one is not actually in hand) from the reproduction cost of the property new, before proceeding to determine the fair return. The question of the correctness of this procedure was not raised until quite recently, and, like a great many other questions connected with the conduct of public utilities, it will probably have to be reasoned out on lines of fairness and justice to both the public utility owner and the public. The rate commissions have not yet discussed this question, nor has it been effectively presented to them, but it is believed that, when discussed, it will be along lines which are here indicated.

Should a Sinking Fund Earn Full Return?—In pursuing this study, the question will be raised as to the propriety of allowing the same full return on sinking funds, when properly set aside in trust as a part of the plant, as is allowed on the plant value itself.

It may be argued, on the one hand, that such funds are free from the hazards of the enterprise proper, that if properly safeguarded or placed in trust, as they might be, they are especially safe and secure, and are free from risk; therefore, they should be allowed only ordinary going rates of interest for secured investments as their part of the fair return on the entire property, and, of course, entirely outside of their own necessary interest accretions.

On the other hand, it may be contended that such funds, generally, are not put in trust, even where set aside, and therefore are subject to call for emergencies in renewals, and partake, in that way, in all the

hazards and contingencies of the plant and property itself, and should accordingly partake of the full returns which the plant and property itself should have.

Inasmuch as the entire question of returns on depreciation funds has never yet been discussed publicly, the attitude of any public utility commission cannot be known in advance, and we will have to await with patience the conclusions of the older commissions which are giving these matters study.

Actual Use of a Full Depreciation Fund.—It may be observed that it is not theoretically possible to expend properly at any one time the full amount of a correctly computed fund for replacement.

Although actual depreciation requirements are not expected to conform to theoretical depreciation funds, nevertheless the two must be so nearly adjusted that funds for renewal closely follow actual requirements. This can only be accomplished by the use of good judgment and experience, in the first instance, supplemented by periodic revisions, as a secondary aid to proper additions to the fund. It would seem that at intervals of not less than 5 years a careful review of the depreciation account of most utilities should be made, and a revision to comply with new conditions effected; oftener would be better in some special cases.

The fact remains, however, that should funds be correctly set aside for renewal and the life of the various structures of the plant be properly estimated, the funds—either sinking fund or as simple increments—could not be wholly or even largely used at any one time; in fact, ordinarily, only a small portion of such fund will be drawn on at any one time. In a sinking fund, if this were not so, the fund would be seriously impaired, as its integrity, to a certain extent, depends on its accretions of interest. Evidently, the short-lived structures will draw on the fund often, and the long-lived structures but seldom; and, where the bulk of the investment is in long-lived structures, it is evident that at least from one-half to three-fourths of the fund might be untouched ordinarily.

This is an added reason, in long-lived plants, why owners now feel inclined to utilize depreciation funds in outside investments, or in betterment to the plant itself; for the remaining portion of the fund that is frequently called on, being small in amount, is easily replaced, and when the larger amounts begin to be needed the fact is long foreseen.

Depreciation Accounts.—Evidently, the keeping of a depreciation account, without setting aside depreciation funds, amounts to only an expression of opinion by the owner as to the lessened value of his property. Such accounts do not finance the depreciation, but, if properly kept, they may tell how much the owner has withdrawn from the value of the plant, and how much he should return, on demand, to make the plant whole.

Past depreciation may very properly be computed on the sinking-fund basis, because this is the close and accurate method when all or most of the life history is known, but the future is much more uncertain. A conservative estimator cannot figure too closely on it; some allowance must be made for the unknown.

The composite life of many water-works plants, for instance, has been found to be between 60 and 80 years. From 0.6 to 0.8% of the total value of the plant, set aside from year to year as an annual increment and put out at interest as a sinking fund, will usually theoretically amortize the principal at the end of the composite or theoretical life.

It is simpler and more conservative, however, to provide a somewhat larger amount in water-works practice, say 1%, as an approach to a straight-line, or even an interest-bearing fund, which may be called "the reserve". Some of the utility commissions are allowing about this amount to be set aside before computing fair return on water-works properties, and it will ultimately be possible, probably, to count on it. Of course, these rates will vary widely in other forms of public utilities; they are cited here only by way of illustration.

In practice, the various structures having different lengths of life should be grouped, so that those of the same life are aggregated, and a separate depreciation account should be opened for each group. The theoretical sinking-fund amount may be computed for each group and entered each month, so that the sum of all the groups would show the amount due to the plant by the owner at any given time. From time to time adjustments will have to be made to correct for errors in judgment as to future life.

If a simple percentage increment is used, the process will be more simple but less accurate, and hazard and unusual accident may be better and more liberally provided for, but the prophecy as to life will not be closer than it can be in the sinking-fund method.

When renewals are made, the depreciation account should be debited with the outside capital replaced in the plant by the owner, and credited by the cost of the improvement.

Should a sinking fund or a reserve fund actually exist, of course, the replacement expense is directly withdrawn from the same in cash.

Summary.—To conclude, then, it has been argued as follows:

1st.—That if a sinking fund or a reserve fund for depreciation is actually kept in the bank or in trust as part of the property, it should, if properly computed and accurately kept, receive the same rate of fair return as the remainder of the property "used and useful for the public".

2d.—That if these funds are for any reason detached or withdrawn from the property and used by the owner elsewhere, or in private gain, or even as new capital invested in the plant itself, he cannot hope. as a matter of proper protection to the public, to receive return on a reserve fund which is not actually in hand and at the same time use such funds for other personal gain.

3d.—That the past depreciation may be computed accurately on the sinking-fund basis, as all the facts of the past are known, and the sinking fund is the most accurate method of computing depreciation, but for the future, in which the facts are yet unknown, it is perhaps better to use the simpler method of an annual increment which will average the sinking-fund rate.

4th.—That depreciation accounts should be kept by groups having similar life, and revised from time to time as the future is more clearly revealed. That such accounts are only estimates of what the owners owe the property, if the actual funds are not in hand.

5th.—That though it is not now considered improper to use reserve or sinking funds allowed for depreciation for private gain, in so doing the owner will in all probability deprive himself of their return earning power as part of the plant and property.

It may be said, frankly, that all the principles which it is endeavored herein to reason out are not yet generally accepted; indeed, the question of allowing fair return on an actual existing sinking fund for depreciation has not as yet been seriously raised.

It is believed, however, that this question must soon be generally discussed, and it has been the endeavor in this paper to reason out in advance the method by which it is believed it will be logically settled.

DISCUSSION

Mr. Wilgus.

W. J. WILGUS, M. AM. SOC. C. E. (by letter).—The distinction made by Mr. Alvord, that the formal setting aside and labeling of depreciation reserves should entitle the owner of a property to a return on the full cost of its reproduction new, and that the non-observance of this technicality should deprive him of that right, does not appeal to the writer as being just or logical. Surely, if the general balance sheet of a corporation shows an excess of assets over liabilities sufficient to offset the accrued depreciation of the property, there would seem to be no more reason why the return should be based on an impaired investment than that the rent paid by a tenant should be lessened if the owner, who has agreed to keep the premises in repair, elects not to maintain a special fund therefor in the bank.

The majority of railroads have ample profit and loss surplus accounts invested in outside securities or in the property in excess of the amount on which a fair return is earned; and this surplus, for all practical purposes, is a depreciation reserve which insures the ability of the corporation to meet its liability of paying for maintenance out of income. A failure by a corporation properly to meet its liability of maintaining the property out of the rate, is usually the result of over-payment of dividends, and eventually brings its own punishment through the necessity of a reduction or suspension of dividends during the period of rehabilitation. This course is obligatory, as charges for rehabilitation legally can only be made through income.

Whether or not a depreciation fund is actually set aside would seem to be immaterial. What the public is interested in is the proper upkeep of the property without an increase, for that purpose, of the capital burden which it is expected to bear through the rate.

As Mr. Alvord states, "* * * no amount of accounting or theorizing can make good a depreciation fund which is actually not in hand"; but to determine whether or not it is in hand may be done just as effectively through an examination of the balance sheet in conjunction with a valuation of the assets, as in looking for a labeled fund in the bank. To "fine" the owner who elects to protect his liability in some other form than by means of a special fund, seems to be rather a drastic punishment for his selection of one of two alternative treatments of an accounting detail.

Mr. Willoughby.

J. E. WILLOUGHBY, M. AM. SOC. C. E. (by letter).—Few engineers will disagree with Mr. Alvord's suggestion,

"That if a sinking fund * * * for depreciation is actually kept * * * in trust as part of the property, it should * * * receive the same rate of fair return as the remainder of the property 'used and useful for the public.'"

Mr. Willoughby.

The writer, however, believes that this suggested addition to the capital account will find little favor. Depreciation is an operating expense when applied to the accounting of a going public utility, and there is no more reason for capitalizing the depreciation item of operating expenses than for capitalizing any other single item, for instance, the wages paid to enginemen in charge of railway trains.

Furthermore, such funds have not been generally provided as a part of the capital account of our public utilities, and we gain directness by discussing the actual conditions, and the need of providing for depreciation as an operating expense, so that the accounting will always show the value of the public utility for any purpose, rate-making or otherwise.

The accounting of a public utility covers other things than the cost of the plant, and it is the ultimate finding of the accounting (exclusive of the speculative and intangible features) that fixes the value of the utility. The author, however, limits his discussion to that "line of evidence as to value known as the reproduction method, or cost new less depreciation." By thus disregarding all other elements of value that enter into a public utility property, the author has no credit account to offset depreciation, except the cost of reproduction new of the physical property of the utility, and he would limit the rates to be charged by the utility corporation to a reasonable return on the capital necessarily expended for a new plant less the accrued depreciation. This means that the utility corporation must, immediately after reproducing its property new, write off as loss the amount of the accrued depreciation, although that accrued depreciation has actually resulted from service rendered to the public, and, although the only practical way of reproducing the physical property will be to invest first capital to the extent necessary to reproduce the property new.

It is generally accepted that the reproduction of the physical property of a public utility which has been in operation for some years so as to show its exact stages of depreciation would be at a greater cost than to reproduce it with all new materials. Consider the difficulty and expense of providing and assembling into a completed structure the curve-worn rails, the partly decayed ties, the partly fouled ballast, the partly failed bridges, trestles, and culverts, and the argument is completed. Consider then the injustice of the suggestion of the author that the property owner should be penalized because of the impossibility of assembling his plant, except as a structure composed of new elements. What the public pays for is service. If the service is satisfactorily performed, as in the railway after some years of operation, over rails, cross-ties, and ballast, each exhibiting but 55% of their cost new, less salvage, and if to perform that service it has been

Mr. Willoughby.

necessary for the owner to expend in the past 100% for those items, the owner should receive a reasonable return on that 100 per cent. The public's protection lies in scanning the operating expenses to see if the charge for maintaining the property is unduly high, as a result of the failure of the railway company to make provision in the past for the depreciation at the time the depreciation actually occurred, and not to deduct from the capital originally expended the amount of the accrued depreciation. It is only after the operating expenses are deducted that any return can be made to the owners of the stocks and bonds. If the operating expenses are unduly high, on account of failure to make provision for the depreciation as it had accrued in the past, the penalizing of the owner occurs in the denial of deduction from the gross earnings of so much of the alleged operating expenses as is due to the failure of the owner to provide for the depreciation at the time of its accruing. The method of penalizing the owner, as suggested by the author—the deduction of the accrued depreciation from the reproduction cost new—is a confiscation of property to the amount of the accrued depreciation, because the amount of the accrued depreciation was originally and necessarily put into the property before any depreciation could take place, and whatever has taken place is properly to be regarded as an expense of operation. No engineer would deduct from the physical elements of a property the operating losses due to bad financial arrangements, extravagance, or incompetency.

To illustrate further: take a cross-tie costing 80 cents in place, and lasting 8 years. For each year following the placing of the tie, there should be charged out as operating expense the sum of 10 cents (less by such interest as it may earn), as the proportion of the cross-tie consumed in that year's operation, so that when the cross-tie is replaced in the eighth year only 10 cents of its replacement cost would be charged into operating expenses, the other 70 cents being taken from the depreciation fund. The purpose of the depreciation fund is to distribute the operating cost of renewal over the number of years that has been taken to consume the tie. Where a depreciation fund has not been accumulated to offset the actual depreciation, the monetary value of such depreciation will go into the profit and loss account as a debit, but there may be such values in that account—like accumulated reserves—which will entirely absorb the debit. Depreciation, when regarded as an operating expense, can never be used to lessen the reproduction cost of a public utility. It will always affect the value of the utility as a going concern.

Every public utility should make provision in its accounting for depreciation, because such an account is necessary to show the annual operating cost of any plant, and to reflect in the accounting the financial and physical condition and value of the plant. It should cover

"all the losses of value that occur in the property, plants, or parts thereof, from wear and tear, obsolescence, or inadequacy." Mr. Willoughby.

For a public utility that has permitted the depreciation to accumulate without providing for an actual fund to offset the same, then the amount of such accrued depreciation (in such event a debit) will go into the profit and loss account, there to be offset by the credit items of other accounts. Correct accounting does not require the actual presence of cash, except as to the amount of the item of cash on hand.

As to what rates are necessary for a fair return for any public utility, if confiscation is not to result to the property in the legal sense: the suggestion is made that the rates should be sufficient to provide for:

1st.—The payment of taxes and other public dues;

2d.—The payment of all operating expenses, including as a part thereof a charge sufficient to care for the annual depreciation that takes place;

3d.—The payment of a reasonable commercial interest (commercial interest being one that considers and includes the element of risk involved) on the reproduction cost new of the property, including the necessary working capital;

4th.—The payment of a like interest on the intangible values of the property and the unearned increment;

5th.—And, finally, the accumulation of funds sufficient to provide for the non-earning additions demanded by the public. The commercial interest earning additions and betterments can be capitalized and becomes a self-supporting part of the cost of the plant.

Frank C. Boes, Assoc. M. Am. Soc. C. E. (by letter).—After reading Mr. Alvord's paper, the writer tried to picture to himself some of the possible results of putting such a system of rate-fixing into general operation. Mr. Boes.

Consider two adjoining and otherwise similar communities served by two power companies, the one having an old and decrepit plant, but still capable of rendering efficient service, and the other having a new and up-to-date plant. The large users of service, of course, would gravitate toward the community served by the depreciated plant, thereby decreasing property values and rents in the community which they left, and making it impossible for the new plant to compete with the old one. The continual see-sawing of rates, due to periodic repairs and renewals, would make it impossible for service rates to reach a standard level, thus making it impossible for a consumer to foretell what his next year's bill for service would amount to, and would also cause much litigation and confusion.

To fix rates purely on a basis of physical value, would remove incentives for good management and economy, and put a premium on

Mr. Boes. wastefulness, expensive plant, and unnecessary repairs and renewals. Over-expenditure on plant, for the sake of keeping the rate up, is more to be feared than a reasonable amount of decrepitude, for, after all, the service rendered is what is paid for.

If such a system were in vogue now, those who live on Staten Island would be paid a substantial sum for riding on trolley cars which have long outlived their years of usefulness and are run by a plant which is in the condition of the "one-hoss-chaise." They are consoling themselves by the thought that they pay, not toward earnings on a dilapidated outfit, but for the service rendered—a 5-mile ride. A company owning a modern plant might give worse service.

Mr. Alvord states that the average life of the component parts should give the composite life of the plant. This must be an oversight on his part, for, assume a plant to consist of two parts, A, costing \$10 000 and having a life of 5 years, and B, costing \$5 000 and having a life of 20 years. Surely the composite life of the plant is less than 12½ years, for its major part is renewed twice in that time.

In fixing rates by such a method, one must also consider that the depreciation curve is not a straight line. It is permissible to establish a depreciation fund by the straight-line formula, for that is merely a convenient method by which the owner may distribute his renewal costs evenly. The amount of the depreciation fund by no means represents the actual physical depreciation, and to base the deduction of rates on an amount which is taken arbitrarily, and is greater than the actual depreciation, would be unjust, particularly if the service were still unimpaired. When a laborer reaches old age, his earning power is greatly reduced, but is he worth less at thirty-five than at twenty? One cannot expect to deduct \$3 000 from a \$10 000 plant, in fixing rates, and still have a \$10 000 service maintained. If the returns are not based on the entire investment continuously, the investment will not have renewed itself at the end of the plant's term of life, and the owner will not have the plant that he had to begin with. Depreciation is merely another form of capital, and must be kept continuously earning returns on its entire amount.

It seems unjust to expect to pay less for service in the fifth year, the service being exactly the same, merely because some parts of the plant will require replacement at a date then nearer than in the first year. Does one pay less for milk given by old cows or for apples grown on old trees?

Mr. Alvord intimates that the reduction in rates should be considered in the nature of a fine, but surely it would be unjust to have a fine imposed, if, when the time for renewals actually arrived, the owner produced the funds and put the plant in shape. What then? Would the amount of the fine which he had paid be returned to him? A man

cannot be fined because it is thought that he is going to commit a crime. Mr. Boes.

An argument sometimes advanced, and by the Courts, is that one should not make one valuation for rate-making purposes, and another valuation for the purpose of sale or purchase; that is, if valuation is deducted in making a sale of a plant, it should be deducted in making the rates of service. Consider some private business: If an owner wishes to sell his factory, he must certainly make a deduction for depreciation, but the price of his merchandise is not affected in any way by the age of his factory or by the condition of his plant. Neither do his customers inquire as to whether or not he has an adequate renewal fund actually in hand. That responsibility rests with himself alone.

Though there is a difference between fixing the prices in a private business, and fixing the rates of a public utility which enjoys monopolistic privileges granted by the public, the fundamental principles remain the same in each case.

The approaching repairs and renewals are an obligation and a cause of worry to the owner, and to him alone. He has to pay for them, and the consumer is in no way concerned with it, as long as the service remains the same. The consumer is not concerned with how near the day of collapse the plant may be, as long as the collapse never occurs. The consumer is concerned only with impairment of service. When that occurs, then a fine may reasonably be imposed.

In fixing rates, one need only be sure that the property is in satisfactory working order and that proper service is being given. The owners can then be left to worry about the depreciation for themselves.

Allen Hazen, M. Am. Soc. C. E. (by letter).—Depreciation has to be taken into account in both the operation and valuation of public service properties. It has to be taken into account because it is one of the fundamental facts that cannot be ignored. Mr. Hazen.

The writer is familiar with depreciation, especially in water-works properties, and what he has to say relates primarily to them.

Allowances for depreciation have actually been made in nearly all properties of this kind. This is not the less true because the amount allowed has not been determined in a rational manner, and frequently has not even been called depreciation. In most public works the first cost has been paid by money raised by the sale of bonds, and a sinking fund has been established, and annual contributions made to it, intended to be sufficient to provide for the payment of the bonds when they became due, thus, in reality, providing for depreciation, even though the word "depreciation" is not used.

Another way of providing for depreciation which has been common, has been to pay for new construction out of earnings. This also is

Mr. Hazen. an efficient means of allowing for depreciation, although the methods and amounts to make it efficient have seldom been carefully thought out. In general, with publicly owned properties, the allowances that have actually been made for depreciation in these ways have been above the truth. This has been fortunate, as the excess has represented only a slight addition to rates which have not been burdensome, and the resulting strong financial condition of the works has tended to good service, worth more than its cost to the takers.

In the relatively small number of cases where no allowance, or an inadequate allowance, for depreciation has been made, there results sooner or later a cramped financial condition tending to bad service, and equally unfortunate for the works and for the takers.

The measure of depreciation for any period is the decrease in the fair value of the property under discussion, or any part thereof. In valuation proceedings, where the cost of reproduction is being considered, the decrease in the value of the property, as compared with the value of corresponding new property, is the measure of depreciation. The fair value of the property is to be considered always as the fair value between a willing seller and a willing buyer. To take a concrete case, it may be considered how much less a willing buyer would probably pay and a willing seller take because the pipes in the streets had been in use for a time, and had suffered the depreciation naturally incident to use. Obviously, some deduction would be made. The carrying capacity of the pipes is less than that of new pipes, owing to rusting and tuberculation; there is more leakage from the joints in old pipes than in new ones, representing loss of water and profits. It may be presumed that the pipes in an existing system laid from time to time are perhaps less efficiently arranged as to sizes and locations than would be the case in such a pipe system as the buyer would lay for himself. These would probably be the most important points to be considered as between the buyer and the seller in deciding what deduction was to be made. In addition, any peculiar conditions of any kind affecting the value of the property would be duly considered.

The average age of pipes in any system in a growing city will ordinarily be from one-third to one-half of the age of the system, and seldom more than 15 or 20 years. The bare fact that an average of 15 years has elapsed in a possible ultimate life of from 75 to 150 years, which is assumed by the author, would have but little influence between a willing buyer and a willing seller.

The case is somewhat different with boilers, which may be assumed to have a life of 20 years, or some other definite period, and will then have to be replaced. The boiler represents the exceptional case in water-works affairs, and not the ordinary one.

The writer believes that there is no such thing as a period that can be called the life of cast-iron pipe. Different pieces of pipe may have useful lives ranging from a few hours to periods so long that they extend beyond our experience. Any statistics that could be collected would contain records of pipes that had been discarded for one reason or another, and would contain, at best, only estimates of the remaining life of the very important part of all the pipe laid that is still in service. The estimates of the remaining life of this pipe cannot be considered to have much value, and averages based on them are certainly no better. Even if the average life of pipe could be ascertained in some statistical way, it would be of little service. What is really wanted is the average percentage payment on the value of all the pipe to be made each year to make good the depreciation lost in it, and this percentage is undoubtedly quite different from the depreciation computed by the sinking-fund method from the average life of pipe, if it could be ascertained. Mr. Hazen.

The writer believes that in the case of cast-iron pipe the gradual reduction in carrying capacity, the increase in leakage from the joints, and the fact that a system now designed might better serve its purpose than an old system, are the dominating factors, and that the elapsed period of life is of secondary importance.

It may be suggested that in using the sinking-fund method it is possible to assume a life for pipe to give any rate of depreciation that is desired, and as the assumed life is pretty sure to be beyond the experience of the ordinary water-works system, it cannot easily be shown to be fallacious. Thus, with a 4% sinking fund, the depreciations corresponding to several lines are as follows:

30-year life,	1.78%	annual depreciation
40- " "	1.05%	" "
60- " "	0.42%	" "
80- " "	0.18%	" "
100- " "	0.08%	" "

Of course, the percentages given refer to the structures only when new. By the sinking-fund rule they would steadily increase with increasing age.

The ease of selecting a life to give any desired rate of depreciation is obvious. Considering the great difficulty, or perhaps rather the impossibility of securing statistics to show the true average life of cast-iron pipe, it may be questioned whether, as a matter of fact, the process has not been reversed, perhaps unconsciously, by estimators, and a life selected which would give a rate of depreciation which has seemed to them reasonable, as judged by other standards. If this is really the case, then the use of the sinking-fund method for computing depreciation may be regarded as a kind of mental ex-

Mr. Hazen.

ercise tending to familiarize the estimator with the workings of compound interest during long periods, and thereby to aid in keeping him from reaching unreasonable conclusions.

The sinking fund has this to recommend it: that it corresponds with practical experience to the extent that depreciation in the early life of a structure goes on slowly, and that as the years go on the rate is increased. There is a tendency to substitute a rule of calculation for judgment, and, as far as the basis of the rule can be well established, this is desirable; and, if a fixed rule is to be used, probably the sinking-fund method of computation is the safest that has been thus far proposed, but it must not be supposed that the real basis of the sinking-fund method is the actual determined life of the structures. It is, instead, the life which practical appraisers find will give rates of depreciation that are in accordance with their experience.

The writer believes that the most logical way to estimate depreciation in the appraisal of a plant is to consider each item on its merits, to determine and take into account its physical condition, its usefulness in the service and the state of the art, and the possibility of substituting other and more efficient structures to perform the service rendered by it. The excellence of the design must be especially considered, and depreciation may be several times greater on a clumsily designed structure than on a well-designed one, although the durabilities and lives may be the same. In a similar manner, a well-built structure suffers less depreciation than one not so well built.

Improvement in methods of pumping, filtering, laying pipes, or performing any part of the service, all have their bearing on the depreciation of similar parts of an old plant. The rule must always be to find what deduction would fairly be made because of all the conditions that exist between a willing seller and a willing buyer fully informed as to those conditions.

In estimating the amount of depreciation to be written off each year, the writer believes that one of the best kinds of information is to be obtained from the financial histories of old plants in connection with appraisals. The question may then be taken up as to whether an annual depreciation of 1% on the cost of reproduction of the property from year to year, made during the whole life of the plant, would have served to have brought the book value to an amount reasonably near the estimated cost of reproduction at the time of the appraisal, and if not, to find as nearly as may be what percentage thus allowed annually would have sufficed to do this. Data of this kind are hard to get, but the engineer having to do with appraisals occasionally has opportunities to secure them. Valuable as these data are, they must be used with caution, as the depreciation of the future is not necessarily measured by that of the past.

The method of allowing for depreciation in the annual operating account is an important matter. The writer recalls the case of trustees who had undertaken the management of an important water-supply system, and who were confronted on the one hand with the difficulty of raising money for urgently needed extensions, and on the other of being required by law to take up a business entirely foreign to that for which they were appointed, namely, that of setting aside a certain proportion of the income from the operation of the property and investing it in securities to be held against the redemption of bonds when they became due. The situation was a trying one, and one that ought not to have existed. Mr. Hazen.

The sinking fund was invented to protect the bondholders who might think that otherwise the city would not be able to raise so large a sum of money on the maturity of the bonds. That is the only possible justification for its existence. If we grant the solvency of the city or company, and assume that they will be able to refund the bonds when they become due, it is better in every way that the allowance for depreciation, or the sum that would otherwise be put into a sinking fund, should be invested in the plant as far as there is need of it.

The author does not know of any sinking fund that has been established for the especial purpose of meeting depreciation. Such a fund as he suggests would be one to which annual depreciation allowances would be paid, and from which money would be taken to replace worn out or discarded parts, and the amount of such a fund, he thinks, would not often exceed 10 or 15% of the value of the plant. The writer feels that the question of whether such a fund is necessary or desirable must be left to those who operate the plant. If it is desirable, he suggests that it might be more appropriately called "working capital", as its function would be quite different from that ordinarily covered by the term, "sinking fund".

It is the writer's feeling that, so far as such a fund of working capital is reasonably necessary and desirable for the proper and economical administration of the plant, the amount of such fund might properly be taken into account in fixing the rates that might be charged without exceeding those that would yield a fair return on the property; but he sees no reason for taking into account otherwise any part of the value of the original plant that may have been lost by depreciation in making such rates. It is clearly the privilege and duty of public service corporations to charge rates that will permit marking off a proper allowance for depreciation. When this allowance has been once determined and marked off, there would seem to be no equitable reason why the capital thus marked off should be further considered in connection with the question of fair rates.

Mr. Vensano.

TABLE 1.—CASE 1.

			Paid by Public.		Paid by Bank.		Available for Replacements and Reserve.		Available for Dividends.	
			Rate.	Amt.	Rate.	Amt.	Rate.	Amt.	Rate.	Amt.
Original investment	$100.00	Allowed as profits	5%	$5.00						$5.00
		" for depreciation reserve	0.83%	0.83				$0.83		
Sinking fund in bank	33.40	Interest			5%	$1.67		1.67		
Investment in betterments, through later security issues	33.40	Allowed as profits	5%	1.67						1.67
		" for depreciation reserve	0.83%	0.28				0.28		
Total paid by public				$7.78						
" " " bank						$1.67				
		Total for depreciation reserve						$2.78		
Total investment	$133.40	Total available for dividends							5%	$6.67

TABLE 2.—CASE 2.

			Paid by Public.		Paid by Bank.		Available for Replacements and Reserve.		Allowable for Dividends.	
			Rate.	Amt.	Rate.	Amt.	Rate.	Amt.	Rate.	Amt.
Original investment	$100.00	Allowed as profits	5%	$5.00						$5.00
		Allowed as depreciation increment	0.83%	0.83				$0.83		
Depreciation reserve reinvested as betterments	33.40	Allowed as profits on depreciation reserve	5%	1.67				1.67		
		Allowed as depreciation increment	0.83%	0.28				0.28		
Total paid by public				$7.78						
Total investment	$100.00	Available for dividends							5%	$5.00
		Total to depreciation reserve						$2.78		

NOTE.—The total, $2.78, to depreciation reserve, represents $2.50, the constant increment on original investment (after 40 years life) and $0.28, a depreciation increment on depreciation reserve (Case 2), or investment in betterments (Case 1). This is proportional to depreciation increment originally provided on original investment.

out, the returns on a bank sinking fund will be less than the returns from similar funds reinvested in the property itself, and therefore the public would ordinarily actually be benefited by such reinvestment, in that the depreciation increment, which must be included in the rates paid, could be reduced. Mr. Vensano.

This should show clearly that a reinvested sinking fund is certainly not a matter of mere bookkeeping.

It may be argued that the fund is not as safe when thus reinvested, but the assumption must be made that, under public service rate regulation, the rates will be adjusted upward when necessary as well as downward, so that a constant and safe return will be obtained from public utility investments, and, if this is done, the reinvestment of money in the property will be the safest possible method of handling such funds.

If public utility investments are not made safe under Government regulation, Government regulation will certainly fail as such, and either destroy the utilities or necessitate Government ownership; because, with uncertain interest returns, held at a low rate, no capital will be obtainable for investment in such utility.

It may also be argued that, up to the time where dividend returns on the sinking fund have reached the state of balance and become sufficient to cover the annual depreciation replacement, a fund reinvested in the property is not in such shape as to afford ready use as cash.

It is to be noted, however, as Mr. Alvord says, that large replacements can generally be foreseen for a number of years, and a new issue of securities can then be provided to cover such replacement; the betterments constructed under the original sinking fund can be then transferred to capital account under the new securities issued, and the depreciation account credited with the replacement expenditures.

A similar reasoning will hold for any outside investment, provided such investment is safe, and provided the returns from such fund are turned back into it and the whole held as a part of the utility, and, as an additional advisable qualification, that such investment be in liquid form. That is, it might be an investment in bonds of other companies which have a ready sale, and may therefore be considered as liquid. Certainly, no one could object to an investment in Government bonds as being any less safe or less real as a sinking fund than such fund held in bank or in trust.

The writer would also like to add that, in addition to believing that any properly kept sinking fund is a good reason for not deducting depreciation in valuations for rate-making purposes, he also believes that, even in some cases where such fund does not exist, it may be proper to omit the deduction of depreciation. Perhaps it would be

Mr. Vensano. better to say that the writer believes that depreciation in general should not be deducted, except in cases where it is clearly shown that the property has been mishandled by the payment of excessive dividends, or mismanaged in some other way, whereby the accumulating of a sinking fund has been prevented, or when such fund has been mismanaged.

Take, for instance, the case of a company which has gone into business recently in proportion to the average life of its properties and equipment. Assume that such company has been in business 10 years, with an average property life of 30 years. In many cases the property might not have paid during its early life, and with the rates at present in force has just arrived at the point where it is able to set aside money for a replacement fund and to pay dividends. Assume that the earnings are sufficiently large to supply a depreciation increment which in the remaining 20 years of life will give the total fund required, which fund, theoretically, should have been started 10 years previously with a smaller depreciation increment. Would it be fair, then, to such company, which has received no return on its investment, and has been unable, because earnings were too small, to provide depreciation increment, to cut its rates now to a basis fixed by a depreciated valuation. Such property without regulation could no doubt be considered a good and well-handled investment, as business investments go, and still would be placed among the class of failures if its rates were calculated on depreciated valuation, as just shown. In any event, if rates in this case are to be based on such depreciated valuation, it would seem only equitable to make them sufficiently high to afford a depreciation increment large enough to return the entire investment in the remaining life of the plant.

It is admitted, of course, that, in using valuations from which depreciation has been deducted, rates can still be fixed logically and equitably by a proper handling of such depreciated valuation and by allowing earning to cover a depreciation increment based on the remainder of the life of the property, as shown by Mr. Grunsky in the paper to which Mr. Alvord has referred.

The whole question as to whether or not depreciation should be deducted from physical valuations for rate-making purposes would seem to the writer largely a matter as to whether or not the public utility had been handled correctly. It is his opinion that Mr. Grunsky's theory is entirely correct, and, as theory, could be applied to any rationally handled property. It would seem that no theory of any kind can be made to apply to a property which has not been handled reasonably and honestly by its management, and at the same time be made to apply equally to a well-managed property.

Where a property has been earning large returns, and has disbursed them as fast as earned, and over and above a reasonable divi-

dend rate; and where, at the same time, no sinking fund has been provided, it is clear that such company has shown itself ignorant of depreciation results as a whole, and therefore must suffer the penalty. Mr. Vensano.

This, however, would not seem to disprove the theory as such, and as argued by Mr. Grunsky, that, in general, depreciation should not be deducted in physical valuations for rate-making purposes.

LEONARD METCALF, M. AM. SOC. C. E. (by letter).—Mr. Alvord's interesting paper illustrates anew by what different mental paths different men have reached similar conclusions. Mr. Metcalf.

As the writer's views on depreciation are consonant with those set forth by the Special Committee of this Society on the Valuation of Public Utilities in its report which will be in print before this discussion, the writer does not purpose to do more than call attention to certain points in the application of the equal-annual-payment method of figuring depreciation, as compared with the ordinary sinking-fund method referred to by Mr. Alvord. The fundamental difference in the two methods consists in the fact that under the equal-annual-payment method, depreciation is treated as an annual amortization or repayment of capital (renewals *per contra* being treated as new construction), and the necessary accretion figured on the sinking-fund basis is assumed to be paid to the owner with the annual uniform depreciation allowance, figured on the sinking-fund basis; whereas under the ordinary sinking-fund method of treatment the necessary annual contribution is made to a sinking fund which must be kept intact until the amortization of the item of property under consideration, in order that the fund may earn its own accretion. Under the former method the depreciation allowance is actually deducted from the value of the property, and the fair return is predicated on its depreciated value. Under the latter method, although the fair return is predicated nominally on the depreciated value of the property, the sinking fund must be allowed to earn its accretions, and, therefore, in effect, the fair return, until the sinking fund on any item of property is complete, must be based on the full original value, as otherwise the owner will be denied a portion of his legitimate return. An examination of the table in the Committee's report showing the annual depreciation allowances on an item of property having a life of 20 years, will make this clear.

Under the equal-annual-payment method of treatment, the annual depreciation allowance is increased each year over that of the previous year by the amount of interest or accretion on the payment of the last year, increasing in an item of property having a 20-year life, for instance, progressively from \$3.02 per annum on the first year to \$7.64 on the last year, if figured on a 5% rate, the sum of the total payments amounting to 100% in the 20-year life. This is in effect equivalent

Mr. Metcalf. to figuring the depreciation by the sinking-fund method on the original value of the property throughout the period of life of this item, as would be done by the sinking-fund method, it being assumed, however, under the latter, that the sinking fund itself shall earn the accretion.

Why, then, it may be asked, is the equal-annual-payment method to be preferred to the ordinary sinking-fund method? The answer is to be found in the fact that the accounting is perhaps somewhat simplified, and, most important of all, that the combined payments of depreciation and fair return are, with due consideration of the increasing cost of repairs during the life of the various elements of the property, made as nearly uniform as practicable, or, at all events, are made much more uniform than by the sinking-fund method as ordinarily applied.

In its practical application, it has seemed to the writer likely to prove advantageous to establish the approximate allowances to be made for depreciation at intervals of 5 years, more or less, and to convert the estimated allowances or rates of allowance into percentages of gross revenue, rather than percentages of reproduction cost, purely on grounds of expediency and convenience in application. Under such a method it might be found, for instance, that 10% more or less per annum of the gross revenue should be charged off to depreciation or amortization of property—renewals, as previously stated, being charged to new construction. Thus the depreciation allowance would grow annually with the increase in revenue, which is, of course, accompanied with increase in investment and value in property.

To attempt to apply the depreciation allowance as a percentage of reproduction cost involves keeping most careful track of the various elements of property or groups of property having lives of different estimated lengths, adding to and subtracting from these groups new plant built and old plant abandoned—a very laborious and difficult accounting problem. Under the other method of application, book accounts can be kept of the deduction on account of depreciation and memoranda of the property which has actually gone out of service. At the stated periods, then, the more difficult task of comparing the assumptions with the facts developed in the 5-year interval can be accomplished, and any necessary changes in rate allowed can be effected.

Under the equal-annual-payment method and commission control, it does not matter seriously if the allowance for depreciation is somewhat larger than necessary, provided it is not seriously burdensome in the rate, for the reason that the rate-payer immediately benefits in the reduced revenue required, resulting from the amortization of a portion of the property. The owner, on the other hand, does not suffer, as he is repaid an equivalent in cash of the property thus amortized.

Mr. Metcalf.

Although, theoretically, if no new construction were added to the property, the depreciated value of the property would gradually decrease, as also the fair return, practically, no such condition is likely to arise, inasmuch as public service corporation properties are operated perpetually, and with the growth which is enjoyed by the majority of American cities the renewals and the new construction required will more than offset the depreciation allowance, so that the actual depreciated value of the property will practically be likely to increase rather than decrease, as will, therefore, the amount of the outstanding securities of the corporation. If, for short intervals of time, this should not be the case, then the repayment of capital through depreciation account could be carried in the bank or otherwise invested temporarily until the need does arise, or it can be used in actually reducing the mortgage debt by a retirement of a portion of the bonds, which bonds could be re-issued at a later date when the funds are required.

In the sinking-fund method of applying depreciation, the easiest practical method of accounting the sinking fund is probably the investment of the depreciation account in the bonds of the company, if the funds cannot be absorbed in new construction, and the keeping alive of these bonds, with the re-investment of the coupon interest on them in depreciation account.

Mr. Alvord's comment, that if depreciation allowances are not used by the owners of public service corporations in renewals, new construction, or amortization of debt, but are used instead for outside investment, the owners must make recognition of such deduction so far as the public is concerned, is sound; and if these depreciation funds be re-invested in renewals or new construction, the writer is of the opinion that a fair rate of return should be allowed on them as allowed on the remainder of the property, and not simply bank interest rates, for the reason that in such investment in the property, hazard is assumed which must be compensated, and it is further to be borne in mind that there is always some loss in interest in the delay in prompt investment of the sinking-fund surpluses which may accumulate from time to time.

In the case of the equal-annual-payment method, it becomes a matter of indifference to the public how the depreciation funds are utilized by the owners of the property, inasmuch as the value of the property on which the fair rate of return is predicated is decreased annually by the amount of this depreciation allowance, and it seems fair and safe under operating conditions to figure the accretions of annual depreciation allowance to be paid to the owner on the basis of rates at which money could be obtained by the corporation with ample security.

Mr. Jackson.

William B. Jackson, M. Am. Soc. C. E. (by letter).—It is not possible for any one who is truly interested in this subject to read Mr. Alvord's thoughtful discussion without receiving valuable stimulus.

In the case of well-established public utility properties, it does not seem reasonable to consider that a sum of money may with propriety be laid aside in a trust fund of which the amount is determined by the amount which the reproduction cost of the physical property new exceeds the physical value depreciated, in accordance with the rules laid down by Mr. Alvord. There may be possible cases where special conditions, such as hazards of the business, might make necessary the laying aside of a sum of such amount, or even more, but the depreciation element of the property, as defined in this paper—and with which definition the writer heartily agrees—can never justify such a trust fund. As must be readily appreciated by any one who has given this matter careful study, only a relatively small part of such an amount is ever required on account of depreciation in usual public utility properties, and, such being the case, how can any one justly permit of a sum of money amounting to from 10 to 15% of the value of such a property to lie for all time in a trust fund. That is exactly what would be done if a public service company permitted a sum equal to the aforesaid difference to lie in a trust fund, and did not differentiate between the part that might be necessary for use in replacement and that which by the nature of things could never be thus used.

In the matter as to whether, in determining the fair value of a public utility property for rate-making purposes, the reproduction value new or the reproduction value depreciated is more important in arriving at a fair value on which the rate of return shall be made, consider for a moment a public utility property from the time of beginning business. At the beginning the company has a right to earn its current operating expenses, a reasonable sum to cover depreciation expenses, a reasonable sum for reserves, and a reasonable return on a fair valuation of its property. If the company is unable to do this during the early years of its existence, it certainly in equity has a right either to add the deficits to its investment on which it may earn a reasonable return, or to have them made up in some other way. When the time arrives when the company can begin to make money, there is no practical reason to require that it shall build up a larger reserve fund than the exigencies of the business require; therefore, it is not logical to assume that the owners have taken out a part of the value of the plant when they have not built up a depreciation fund to an amount which is entirely unnecessary for the most economical and reliable operation of the property. It is equally illogical to assume that any part of the earnings of the property should be considered as constituting such an unnecessarily large fund.

The writer believes that undue importance is placed on depreciation of plant *per se* without due consideration being given to the question whether the property has been kept in such condition as to give substantially as good and economical service as a new property and is fully safeguarded by its reserves from financial breakdown. Mr. Jackson.

In this the writer does not wish to imply any lack of appreciation of the vital necessity for a vigorous carrying out of a safe depreciation programme, and his position in these matters is fully attested in his paper on this subject early in 1910 before the Western Society of Engineers, and in his discussion written in 1911 for the American Academy of Political and Social Science. There is undoubtedly no more unavoidable expense to be met by any public utility company than depreciation expense, that is, the expense for renewals of outused plant.

F. Lavis, M. Am. Soc. C. E.—It has always seemed to the speaker to be much easier to visualize depreciation and place a value on it than to estimate appreciation properly. He is inclined to agree with the author, that it can be demonstrated, at least from a purely theoretical point of view, that when depreciation is not offset by an actual sinking fund, its value should be deducted in order to obtain the present value of physical property. When, however, valuations of railroads are made for the purposes of rate-regulation or rate-making, it seems as if there might be good reasons for not making the deduction. Mr. Lavis.

The discussion which follows is confined to the effect of this theory on the valuation of the properties of railroads, as the speaker's experience has been principally with this section of the industries of the country coming under the general heading of public service or public utilities companies, and though it is probable that the general principles may hold good in any case, there may be some inherent differences in connection with the properties of some of the other sections, such as lighting, water supply, etc., with which he is not so familiar, which when applied to them might modify the conclusions.

It also seems best to confine any discussion of this subject to cases where the depreciation is normal, that is to say, in the case of railroads, where the plant, roadbed, equipment, etc., is maintained in such condition as to give the public reasonably full and efficient service, which with the present close inspection and regulation by the National and State authorities, should be true of most railroads. Abnormal depreciation, in any event, requires special treatment, as a reduction of rates, of course, would not tend to build up a property which is badly run down.

The theory that depreciation should not be deducted when valuations are made for the purpose of establishing rates has been advanced

Mr. Lavis. by C. E. Grunsky and W. J. Wilgus, Members, Am. Soc. C. E., in papers recently presented to the Society, and by H. P. Gillette, M. Am. Soc. C. E., in a brief recently submitted to the Public Service Commission of the State of Washington. Mr. Alvord also points out other differences of opinion in regard to this matter, and intimates quite truly that a proper understanding of it is not easy.

If a sinking fund is maintained to cover properly such depreciation as there may be, there can hardly be a difference of opinion that rates should be based on the full value; to this the author agrees. If, however, a sinking fund is not maintained, he claims that the value is not in the property, and, therefore, the public should not be asked to provide interest on such full value. He points out also that, in the United States, sinking funds are not usually maintained. In reference to this it may be noted that a sinking fund of 10% on the capitalized value of our railroads would amount to about $1 500 000 000—much more capital than we can afford to have lying idle.

In order to understand the argument of those who claim that depreciation should be deducted, in cases where a sinking fund is not maintained, take a concrete example: for instance, a new railroad, the value of which, for convenience, will be assumed to be $100, and a fair return on the investment as 7 per cent. Assume, also, that the rates provide for the establishment of a sinking fund.

At the end of 10 years the road is rendering full and adequate service, though parts of its structure and equipment show signs of wear. The roadbed, etc., in the meantime has consolidated and its value has appreciated. Assume, however, for the purpose of the argument, that after allowing for the appreciation, etc., the net value of the depreciation is 10 per cent. The actual value of the property would then be $90 and the sinking fund would be $10.

Under these conditions it will be admitted that the rates should still be maintained to provide the 7% on the amount of the full original investment, inasmuch as the sinking fund produces nothing.

During the period under consideration the annual revenue and expense account of the railroad might be approximately as follows: (Round numbers are taken for the sake of clearness.)

Operating cost	$12
Sinking Fund	1
Interest	7
Total	$20

Now, suppose that during this period the dollar, instead of being added yearly to the sinking fund, is paid out in dividends, which have been 8% instead of 7%, so that at the end of the 10 years the $10, instead of forming the sinking fund, have gone back into the pockets

of the owners, then, it is claimed, the public should not be asked to pay rates on the full $100. If the case in actual practice were as simple as this, there would be little need of further argument. Mr. Lavis.

The practice in the United States, however, has not been to establish sinking funds, which produce nothing, but often to put the money back into the property for betterments.

In the case of a new railroad, such as the speaker is considering, as a temporary measure, some of the slopes in the cuts are not fully taken out or not trimmed up until after it is put in operation; the line is not completely ballasted; settlement of embankments has to be taken care of, and so on. Much of this work is done during this first period with the 1% which would have gone to form the sinking fund. Later, the surplus earnings go to provide for reduction of gradients, improvements of alignment, elimination of level crossings, etc.

In Europe and in most other countries of the world, except in North America, all such work is usually charged to additional capital expenditures, and it is largely for this reason that the capitalized value per mile of railroad in Europe is so much greater than in the United States, the capitalized value of English railroads being almost twice as great. There is some idea that railroads in Europe, and particularly in England, have cost more because they are so much better; this, however, is not so, at least not nearly to the extent of the very much greater capitalization.

In regard to betterments and improvements paid for out of earnings, the argument, of course, is that in a properly made valuation of an existing property, the appreciation due to money spent for betterments and improvements will be duly allowed for, and that when it is, depreciation due to actual wear and tear should be deducted, in order to get the true fair value of the property in use.

If appreciation of the thousand and one improvements in the property of any well-established railroad can be properly allowed for, well and good, but, to the speaker, this seems at least somewhat difficult, whereas there is never any difficulty in allowing sufficient depreciation, so that, after all, the question resolves itself into the ability to make a true valuation of the physical property.

There is no doubt that a fair and just valuation, equitable alike to the public and to the owners, can be made, but that it can be mathematically exact is practically impossible, and because there is so much more probability of over-estimating depreciation and under-estimating appreciation, one may very well hestitate before deducting the former from a valuation to be used for the purpose of fixing or regulating rates.

In most of the valuations which have been made public, the so-called present value has been estimated to be from about 10 to 15% less than the estimated cost of reproduction new. In some cases ap-

Mr. Lavis. preciation due to the consolidation of the roadbed, etc., has been allowed, but apparently the net result is to show a present lesser value, and, according to figures generally accepted so far, the normal depreciation of a well-managed and properly maintained railroad is assumed to be about 10 per cent.

It seems to the speaker that this amount might well be, and probably generally is, offset by what might be called "not easily apparent appreciation." Any railway man of experience can easily imagine work of a physical character done on a well-established road, 20, 30, or 50 years old, which is not easily apparent, the worth of which, however, still exists.

In an article* describing the construction of a railroad recently completed near Kansas City, the Chief Engineer makes the statement that "Owing to the newness of the road, the train schedules are not yet as fast as they will be later."

In another article,† describing some recent new work on an improvement of the Nashville, Chattanooga and St. Louis Railway, occurs the following:

"On the new roadbed a heavy bed of cinders is used for ballasting, as this is more easily surfaced during the inevitable settlement of the fills, and forms eventually a good sub-ballast between the roadbed and the permanent stone ballast."

These, of course, are only specific instances of what all experienced railroad engineers know, but it seems as if the importance of this phase of the valuation question is not always fully realized, largely because many of the values thus introduced into a railroad property are not easily apparent.

There is no possible doubt that any of our modern trunk-line railroads are better transportation machines as they stand to-day, with rails and ties partly worn, with other parts of the equipment showing some wear, than they would be if we were able to replace every part in a brand-new condition. Theoretically, by taking specific instances of parts of the railroad machine, such as rails, ties, or rolling stock, one can easily visualize and value the depreciation, but it is known that the well-established railroad, as a whole, is a better and more efficient machine to-day than it was the day it was built.

Knowing this, and there can be no doubt of it, there is something wrong somewhere with a theory which gives a lessened value to a machine which is better than new, and it seems to the speaker that the trouble principally is, not the fact that depreciation is calculated and allowed for, but that appreciation is not appreciated.

In estimating the value, whether for rate-making or for any other purpose, of the purely physical elements of the property of a rail-

* *Engineering News*, October 9th, 1913.

† *Engineering News*, October 23d, 1913.

road, depreciation may be estimated and deducted, but one should also be sure that full value is given to the appreciation, to the development costs, and to the other elements which go to make up the efficient transportation machine. Mr. Lavis.

Mr. Humphreys.

ALEXANDER C. HUMPHREYS, M. AM. SOC. C. E.—The reading of this paper should help to emphasize a responsibility which to-day rests heavily on the engineers of the United States; namely, to educate the public and their representatives in legislatures, commissions, and Courts, many of them necessarily ignorant on the questions involved in valuations and rate-making. Here we, the engineers of the country, are charged with an especial responsibility because of our specialized training. First we should, among ourselves, do our utmost to form right judgments on these momentous questions. It is with great regret, therefore, that the speaker finds himself almost completely out of accord with the views expressed in this paper.

We are to-day passing through a period of trial for our form of government. Therefore the speaker feels particularly that, with regard to all public questions, we must frankly express our honest opinions. This is the only way left to meet effectively the mass of bad advice which is being fed to the public.

In the first lines of the paper it is stated: "that space will not be taken here to review fundamentals". The author then proceeds to discuss the very fundamentals of the subject of depreciation, and to support views which, in the speaker's opinion, are fundamentally wrong.

As the speaker understands the paper, the author is attempting to confine himself practically to "the relation of depreciation to cost new", which, he says, is "vital", and that only one line of evidence (reproduction cost new) is to be considered. The speaker is not prepared to agree that "other lines of evidence are equally important before arriving at value".

Mr. Alvord then refers to some writers who have and have not agreed with him, and continues:

"Here, therefore, there seems to be a very serious disagreement, among authors who have written recently on this subject, as to whether or not depreciation should be deducted from the cost new of a property for finding value for rate-making purposes where the reproduction method is adopted as a basis of value. It seems to be desirable, therefore, to present a further study of this question."

Certainly, this paper makes it more than ever desirable that there should be further study of this question. Although the speaker is overwhelmed at the present time with duties accepted, he feels that he would be delinquent if he did not contribute his little share in this much needed discussion.

Mr. Humphreys.

Mr. Alvord says:

"The sinking-fund method seems to be an accurate way to compute depreciation where all or most of the life history is known, as it consists largely in finding past depreciation."

First, the speaker objects to the use of the term "accurate" in connection with estimates on depreciation to accrue. Again, he objects to the intimation that it can be assumed as a working basis that "all or most of the life history is known." This life history in large part must depend on the books of account and other records, which frequently are incomplete, and, even when complete, have been influenced by many changes in the system of accounting.

Again, in many cases, the existing company is the consolidation of many smaller companies, the books of which are often not available, and if available are found to be not self-explanatory. It would appear as if it should not be necessary to say to men of experience anything more, or even as much as the speaker has said, on this point.

The author then says:

"The sinking-fund method of computing or allowing for depreciation consists in determining the proper useful life of the structure or machine under consideration."

Here he appears to be confusing estimated accruing and accrued depreciation with actual depreciation; but let that be as it may, who shall say authoritatively what is the "proper useful life" of any part of a plant. There are those who assume that the life of parts of plant can be found by reference to tables prepared by so-called experts; but surely this absurdity cannot be supported by men who have had experience as constructors and operators. To determine how much should be allowed for annual expenses or cost, we may well estimate the life of each part of a plant, knowing that these figures may prove to be far from the fact; and hence we are justified in making a liberal estimate for this purpose.

Here, however, we must never forget the underlying reason for this estimate and the journal entries based thereon, namely, to spread the cost of final renewals as uniformly as possible over the periods benefited, so that we shall not deceive ourselves as to losses and consequently as to profits. Especially should we be careful not to over-estimate our profits, and hence we should be sure not to under-estimate the cost of final renewals.

The speaker wishes that the term "depreciation" had never found favor. Much of the present confusion of thought on this subject would be avoided if only the term "final renewals" were used.

Here at once it is seen that such an estimate should not form the basis for determining present depreciation. This should be determined as closely as possible by the exercise of engineering, managerial, and

accountancy ability, based on academic and practical considerations, chiefly the latter. Mr. Humphreys.

Here we have the all-important difference between estimated accruing depreciation as an element of cost, and actual depreciation in establishing the present value of an asset; this last by actual expert examination, having in mind physical decay, obsolescence, and inadequacy.

Again, Mr. Alvord says:

"In case a portion of the life has passed away, the present value of such structure is assumed to be, in a general way, the present cost of replacement new, less the accrued amount of the depreciation fund to date."

The speaker has just shown why the amount in the sinking fund may properly be quite different from the actual depreciation. It is based on an estimate made in advance, and on many assumptions. In making an appraisal we have before us the present facts as to physical condition, obsolescence, and inadequacy. In the first case we have foresight, and in the latter we have the advantage of backsight.

To determine the actual cost, would one go to an engineer's estimate of the cost of some large construction, or to the record of the money actually expended, which would cover all omissions, contingencies, overhead charges, etc.? If the first course were taken, the speaker fears that the business world would be more than ever critical of engineers' estimates, which have so often misled investors because of the omissions referred to.

Supposing the existence of an approximately correct determination of the actual depreciation to date, the speaker contends most emphatically that, although perhaps the plant is thus reduced in value, no deduction therefore should be made in a rate-making case.

In meeting this proposition, the question is asked frequently: "Would you pay as much for an old plant as for a new plant?" and the questioner thinks that the question settles the matter.

Not so. As a purchaser, if there were any real depreciation, the speaker would claim a reduction. Why? Because he has to assume the liability for the final renewal of the plant. In a rate-making case, however, that liability still rests on the owner, and therefore the plant must be considered as maintained or to be maintained by the owner.

Mr. Alvord, strangely enough, admits that "no deductions from cost new or reproduction cost, where that method [actual establishment of a sinking fund under trust conditions] is being used, would be necessary". Then he says:

"Where a proper depreciation fund is not set aside actually, but is only estimated and written off in the accounts, there is no such condition, and the matter of writing it off by the owner in his books amounts

Mr. Humphreys. to only an opinion of his as to what such depreciation fund should be, but does not at all produce such a fund, or make it available; in consequence of which, an appraiser, using the cost new or reproduction method as one of the means of arriving at the value of the property, and finding no depreciation fund actually in hand or in trust, is obliged to deduct it from the property."

Is the appraiser "obliged" to deduct because of an opinion thus expressed?

Mr. Alvord shows that the owner is alive to the fact that depreciation is to be cared for, and that he refuses to inflate his profits by ignoring that fact. By his act he shows that he is liable for the cost of renewal, and that this item of cost must be obtained from income. A buyer would trade on this admission to get a lower price, but, as before shown, even then it by no means follows that the seller would have to deduct the full amount thus written off. That is not a question of the fair determination of values and the fair fixing of rates, but of bargaining.

Mr. Alvord then proceeds:

"In other words, no amount of accounting or theorizing can make good a depreciation fund which is actually not in hand. A clear perception of this principle will save much confusion of thought."

Here Mr. Alvord mistakes his assumption for an established fact. The speaker fears that that is a weakness throughout the paper.

The Standard Dictionary defines "Principle", in part, as follows:

"1. A source or cause from which a thing proceeds; a power that acts continuously or uniformly; a permanent or fundamental cause that naturally or necessarily produces certain results. * * * 2. That which is inherent in anything, determining its nature; essential character; essence."

Here, then, it is found that, notwithstanding his disclaimer, as before referred to, Mr. Alvord is discussing fundamentals.

The speaker presumes that much confusion of thought might be saved if all were prepared to adopt blindly Mr. Alvord's dicta and then refuse to confuse their minds by further independent thinking.

Now, to come down to facts: Assets are widely variant in character. Cash is an excellent asset, if the money is honest money. Particularly is it valuable in emergencies because it is liquid. Usually, it is a promise to pay, on the part of the government, of a bank, or, if not in actual cash, it might be a promise to pay by the trustee of a fund; but government or bank promises to pay are not always made good. There has been no little repudiation, even in this enlightened country. Or, government notes may be greatly depreciated. We have also had that experience in the United States, a condition corrected only by the courageous act of a great President now passed to his reward. Still

Mr. Humphreys.

more, the trustee of a fund may default—not an unknown occurrence. Now, if the owner is solvent and agrees to make good the loss due to depreciation, that is, to renew the plant, and this assumed liability is shown on the books, there must be a corresponding asset, or else money not earned has been paid out in dividends. The entries referred to, however, have been made to guard against such a ruinous course. Naturally, the speaker is not referring to fraudulent bookkeeping or fraudulent management, but is following Mr. Alvord in assuming normal conditions and management.

This asset, if not in cash retained, will in all probability appear in additional plant paid for from earnings, and may be regarded as borrowed from the depreciation reserve. The fact is that where the depreciation reserve is treated in this way it has to be borne in mind that all parts of plant which appear in the appraisal inventory as having been paid for from the depreciation reserve fall in one of two classes:

1.—Parts which have been installed as renewals or replacements, and are, therefore, in place of parts represented in the original investment, and hence to be included as such;

2.—Parts of plant which have been installed as extensions or betterments, and have been paid for with money borrowed from the depreciation reserve.

These parts, therefore, should be included in the inventory and appraisal, because they are not duplications of investment, but represent additional investment.

In the case of an interest-bearing depreciation reserve, the balance to the reserve should be credited each year with interest at the rate agreed on. Then the money thus borrowed has to be returned when required for final renewals, and must be repaid from capital. In the meantime the company has been able to defer the day for final financing. These extensions and betterments can be considered as capital investments, the amounts borrowed from depreciation reserve standing as a liability against the owners. In reference to this matter, the point may be made again that, whether or not there is a depreciation reserve, the liability for renewals rests against the owners. The setting up of the reserve is, as before shown, to spread this item of loss as uniformly as possible over the periods benefited. The loss due to final renewals will occur in any case, though not exactly in the amount estimated.

Mr. Alvord then attempts to show that the deduction for depreciation would not lead to a progressive reduction in the rates. This discussion he carries on under the headings, "The Attempt to Simplify the Question", "Perpetual Life", "Utilities Commonly Require Grow-

Mr. Humphreys.

ing Plants", "Earning Power of the Depreciated Plants", "Natural Accretions", and "Sinking Funds an Inherent Part of the Plant".

The speaker agrees with some of the statements he makes under these headings; but disagrees absolutely with his conclusions. On page 796 the author states:

"It is clear, therefore, that, as far as valuation for the purpose of sale is concerned, it is right and proper that, in the absence of actual sinking funds or any sufficient reserve fund, they should be deducted from reproduction cost or 'cost new', when that method is used to ascertain value. Does not this also hold good in the case of valuation for rate-making?"

It is presumed that the author looks for a reply in the affirmative to this question. The speaker unhesitatingly replies in the negative; and this, it is thought, is where Mr. Alvord and his many adherents go astray.

The case of purchase and sale has nothing to do with the question, and the author has supplied, presumably unconsciously, many arguments to support this position. What he has to say under "Perpetual Life," can serve as an example.

What the public is concerned in is the quality of the service rendered. That is the test. It is for the commissions to see that the service is adequate in quantity and quality and that the investment and its return are not exorbitant.

In purchase and sale, it is a case of bargain. It may be a case of turning a fixed asset into a liquid asset. There may be many reasons for the owner's willingness to sell well below value; but in any case he should be willing to deduct fairly for accrued actual depreciation, because the buyer has to assume the liability therefor. If the seller can turn over a sinking fund, which in the opinion of the buyer is a sufficient offset to depreciation, then his liability therefor is covered. All this provided this is the best bargain he can make; for bargain it is.

Under the heading, "The Practical Treatment of Depreciation Accounts", Mr. Alvord takes, as an example of the point he is trying to demonstrate, the case of "a railway having extra rolling stock which is only needed at certain seasons of the year when the traffic amounts to a maximum". Then he shows that the property would not be as valuable if this extra rolling stock were sold, relying on the chance of buying it back when actually needed. Again, the test is one of service. If this rolling stock had been sold before the appraisal were made, and not replaced, naturally the decrease in value would be reflected in the appraisal. If all the property had been sold, it would have a still greater effect on the appraisal, because no appraisal would be necessary.

To wind up this part of the discussion Mr. Alvord says: Mr. Humphreys.

"To state it in another way: a utility company plant is not as valuable to the public without a reserve fund for replacement as it is with such a fund intact and on hand and promptly available."

This is not stating it in another way, but is an entirely different proposition. The reserve fund is a matter of finance. The cars might not be purchasable for immediate delivery, but this by no means shows that money for replacements could not be obtained simply because there was not cash enough on hand. Such a case is almost unbelievable, provided the owner enjoyed the ordinary good credit of public service corporations. Again, it is a question of service, and the public is not interested in the financing of the replacements provided the amounts thus expended do not add to the capital burden.

Under the head of "Outside Investment of Depreciation Funds", Mr. Alvord objects to investing the depreciation reserve in betterments which might give 7 or 8%, instead of the guaranteed 3½ to 4 per cent. He refers to "the general risk incident to the enterprise". As all the capital invested is subject to this risk, there is no good in splitting hairs about this particular part of the investment; but Mr. Alvord thinks that it works an injustice to the public if the owner gets a return on these betterments. If the return has been allowed for in the amount annually to be set aside, it does not. The returns are in lieu of the interest otherwise allowed by the banker who holds the depreciation fund, and these returns are required to bring the reserve up to the required amount. As to the extra rate of earning, there can be no injury to the public if the property prospers because of this or any other saving. Also, the speaker imagines that Mr. Alvord has failed to appreciate the fact that, as a rule, extensions thus made do not pay a high return at the start and are frequently made in advance of a paying demand for the service.

The speaker, as a manager, has had to face this problem in not less than fifty cities in the United States.

Under the head of "Present Practice" Mr. Alvord says:

"The rate commissions have not yet discussed this question [that of deducting a 'theoretical depreciation fund'], nor has it been effectively presented to them, but it is believed that, when discussed, it will be along lines which are here indicated."

Believed by whom? The speaker quite disagrees as to the correctness of the statement. He can hardly think of any question which has been more discussed in the cases of which he knows. He also ventures to believe that the questions involved have been "effectively presented". The statements have not always been understood, for those to whom the statements and arguments were addressed were in some cases, through lack of training and lack of experience in the several lines

Mr. Humphreys.

of construction and administration, incapable of understanding the matter presented.

Under the head of "Should a Sinking Fund Earn Full Return", Mr. Alvord says: "We will have to await with patience the conclusions of the older commissions which are giving this matter study". Again, the speaker completely disagrees with him. It is not for us to "await with patience", or with impatience, the conclusions of the older commissions, or the younger commissions, on any point. It is for us to go ahead with open minds to determine what we believe is fair and honest to the public and public utilities, and to do our best to educate the public and the commissions. If they are right and we are wrong, it is for us to acknowledge the fact; it is for them to do the same. It by no means follows that we are to accept as correct the rulings of the commissions simply because we have to govern ourselves thereby until these decisions are reversed. Even the Supreme Court of the United States is not infallible.

The speaker also objects to the reference to the "older commissions", as if they of necessity were most likely to give just decisions. That does not follow. There may be an old commission with a new personnel, and "the last state may be worse than the first".

Under the head of "Depreciation Accounts", Mr. Alvord indicates that in his opinion the cost of depreciation should be estimated liberally. He says, "Some allowance must be made for the unknown"; also, "From time to time adjustments will have to be made to correct for errors in judgment as to future life". This is quite true; but the unknown has not happened when the rate-making appraisal is made, and if no "adjustments * * * to correct for errors in judgment" have been made, how about deducting from cost new the full amount thus accumulated in the reserve?

In the speaker's experience the so-called experts testifying for the people deduct the depreciation according to an assumed "average life", and they do not worry about the "unknown" or "errors in judgment". They are so used to dealing both in the unknown and errors in judgment that they have long since ceased to worry.

On page 803 Mr. Alvord says:

"When renewals are made, the depreciation account should be debited with the outside capital replaced in the plant by the owner, and credited by the cost of the improvement."

Is this one transaction which is referred to? Is it a replacement? If so, is it an improvement? Of course, a replacement may include in part the element of improvement, but this hardly seems to be what is intended. To what account is "the cost of the improvement" to be credited?

The speaker does not find this a self-explanatory direction for a journal entry, and would suggest that it be rewritten.

Now, as to the several items of the summary: Mr. Humphreys.

1.—This is incomplete.

2.—The speaker disagrees with this, absolutely.

3.—"All the facts of the past" are not known. The sinking fund is not the most accurate method of computing depreciation. The depreciation has to be estimated before the sinking fund can be computed.

4.—This is quite correct, and furnishes an answer and contradiction to much that is in the paper.

5.—The reference to "private gain" is not clear. If the speaker understands the statement, he considers it an unfair proposition.

In his concluding words, the author says: "all the principles which it is endeavored herein to reason out are not yet generally accepted".

The speaker is glad to be able to agree with Mr. Alvord here; but must go farther and express the hope that most of these "principles" never will be "generally accepted". They cannot be accepted without working confiscation in some degree.

In conclusion the speaker begs to refer to a paper recently written by him which discusses at length most of the questions raised by Mr. Alvord. This paper is entitled "Depreciation, Estimated and Actual." It was presented in June, 1913, before the Institution of Gas Engineers of Great Britain, and has been reprinted in many of the technical journals of the United States, and also in pamphlet form.

In this paper the speaker supports the proposition that no deduction should be made for depreciation if the property has been adequately maintained, and particularly that no deduction should be made on account of aging of the plant. He draws the line sharply between estimated accruing depreciation and actual present depreciation, the latter as found by expert examination at the time. He also shows that in not a few cases there is no need for any estimated depreciation because the current final renewals make a fairly uniform annual charge, and this applies to properties as a whole, and in many more cases to parts of properties, so that those parts can be eliminated from the estimate of accruing depreciation.

Henry Floy, M. Am. Soc. C. E.—Without discussing in detail the points made by Mr. Alvord, some of which are well taken, the paper, as a whole, is wrong in its conclusion and unfair both to the utilities and the public. Mr. Floy.

The author bases his paper on two assumptions—which he does not attempt to prove—both of which are false:

First.—That both newly originated and long established utilities must be treated alike.

Second.—That a depreciation reserve fund is a necessity.

Mr. Floy.

Before undertaking an intelligent discussion of this subject, there must be drawn a sharp line of demarcation as to whether the valuation being considered is that relating to an existing and long established corporation, or one which has originated under public service regulation. The same rules may not fairly be applied equally to utility corporations so differently originated.

In a case of property constructed and put into operation before the creation of regulating commissions, the investors, with the consent of municipal, State, or Federal authorities, and the sanction of the public at large, were allowed to do certain things which are no longer permitted under utility regulation. Where a corporation is created and the money of the owners is invested, after notice, under conditions prescribed in advance by regulating bodies, there can be no fair or honest objection to the insistence on accumulation of depreciation funds out of revenue and the use of such funds in any reasonable way, but they cannot necessarily be used as a measure of the value of the property on which rates are to be fixed. With respect to corporations that have been in existence for a considerable period of time without commission regulation, and have been following certain generally accepted principles with the consent, more or less definite, of public authorities, the speaker takes emphatic exception to the proposition, advanced by the author, that value for rate-fixing purposes must be determined by deducting the amount of a computed but not accumulated reserve fund from the cost of reproduction new. The arguments presented in the paper may be reasonable when applied to some newly organized corporations, but they are unfair as applied to most existing corporations. The point to be made clear is that no *ex-post-facto* rulings should be attempted by commissions or countenanced by such organizations as the American Society of Civil Engineers, simply because no reserve fund is in hand. Who shall say that, because utilities had not accumulated reserve funds before public regulation was instituted, therefore, the corporations shall now be deprived of a part of their property. In determining rates where the public and corporations have consented to the existence of a certain thing in the past that is not legally or criminally wrong, and about which there still exists honest differences of opinion, it is not fair or right, in making rulings for the future, to attempt to apply such rulings to the past at the sacrifice of investment or the jeopardy of income. It is on this point—the difference between a corporation already in existence and one originated under new laws—that the mistakes have been made in the rulings of commissioners who, for the most part, inexperienced in utility corporation affairs, have attempted to apply theoretically perfected methods which are largely the result of development and experience. It is the old truth, that the same medicine will make some men well and others ill.

That the so-called, though misnamed, present value is not determined by the cost new less the amount of depreciation or reserve fund is indicated by the fact that a fund accumulating for a period of years, based on the original investment, would probably result in too small deduction from the reproduction cost new in case of investments which have enormously increased in value, and too great deduction in the case of those which have largely decreased in value. Mr. Floy.

In the second instance it may certainly be questioned whether there is any necessity for the accumulation of a reserve fund for the purpose of ultimately returning to the investor full value of his property, except in a case of limited franchises or where the lives of utilities are definitely determined. Although in most cases a moderate reserve fund should be kept in hand for contingencies, it is a fact, as has been argued for some years by the speaker, that there are utilities which do not require the accumulation of any depreciation reserve funds whatsoever. A corporation which has its property widely distributed, of various characters, with single units of relatively small value, may not require any depreciation reserve because the deterioration of property—after the first few years of operation—is taking place at an approximately uniform rate per annum, and, therefore, all depreciation becomes wear and tear and is taken care of as a part of the annual operating expense; as an example the Third Avenue Street Railway Company, of New York City, may be cited. This property consists of nearly 300 miles of surface track, partly overhead and partly underground trolley, with rolling stock to correspond, of all sizes and types, as well as storage battery cars, underground conduits, cables, overhead transmission systems, car barns, sub-stations, generating station, real estate, and other property extending from the lower end of the Island of Manhattan up to and through the Bronx and the County of Westchester, so that the exhaustion of any physical property, as far as can be anticipated, will not result in unduly increasing operating expenses for its replacement, or affecting net income, or in any way jeopardizing service or charges to the public. Despite the orders of the Public Service Commission to do so, the Third Avenue Company accumulates no depreciation fund, and yet is operating most successfully.

Why, then, should Mr. Alvord argue that this company should have on hand a reserve fund equal to 15 or 20% net value of its property, say, from $9 000 000 to $15 000 000, for which the corporation has no use, except to be allowed to earn fair return on this property under his theory.

On page 798, Mr. Alvord says, "a public utility owner, under such circumstances, is tempted to let his plant run down, and withdraw from the property the funds necessary for its renewal from time to time, and use such funds for his other gainful purposes." Except

Mr. Floy. under abnormal conditions, this statement is not in accordance with the facts. Valuations of a large number of utility properties of different kinds, made by a host of independent and separate appraisers, result in showing that the average condition of these properties is between 80 and 90% of reproduction value after deducting the amount of depreciation, as determined by methods suggested by Mr. Alvord, or the straight-line method of calculating depreciation which shows even a smaller present value than Mr. Alvord's method. Consequently, it may be stated, without fear of contradiction, that the condition of the average utility plant is not run down, whether or not reserve funds are maintained. Moreover, utility regulation provides for proper maintenance and service, and this can be enforced and secured even to the exclusion of dividends. Take the case of a corporation which has issued only stock, and has no bonds or mortgage indebtedness outstanding—as is not unusual, particularly in New England—in such a case, the entire interest of the stockholders is a guaranty of good service. Why, then, must the public be further protected by an unwieldy and useless reserve fund, which is of no service to the corporation, except to permit it to earn on the full value of the property?

Mr. Burns. Clinton S. Burns, M. Am. Soc. C. E. (by letter).—The question as to whether or not depreciation should be deducted from the cost new of a property in finding the value for rate-making purposes where the reproduction method is adopted as a basis of value, is one that has often suggested itself to the writer, but not until recently has he undertaken to make a comprehensive analysis of the subject with regard to the equity of the points involved. Considering the case of the most simple proposition, as cited by the author, where the composite life of an entire plant has been estimated, at the end of which the plant would be subject to entire renewal; that is to say, the original investment will have completely disappeared at the end of this estimated life, the following analysis suggests itself:

First, let it be understood that the obligation to renew the property, or any portion thereof, is a liability of the public utility company, and if the company has not the cash in hand with which to meet this liability, it must assume the burden of financing the necessary renewals whenever the necessity may arise, and as far as the public is concerned, it is immaterial whether it chooses to provide in advance for the financing of renewals by setting aside its annual accretions to the depreciation fund, or, whether it chooses to make other uses of these funds and then re-finance the renewals when the necessity arises—provided, however, that it is strong enough to accomplish such re-financing promptly when called on to do so. Furthermore, it is now conceded by all authorities that the obligation to renew the property, or, in other words, to make good the depreciation, is very properly transferred to

the public (the rate-payers). This is expressed in substance by the Supreme Court of the United States in the Knoxville case in the following words: Mr. Burns.

"The Company is not bound to see its property gradually waste without making provision out of the earnings for its replacement. It is entitled to see that from the earnings the value of the property involved is kept unimpaired, so that at the end of any given term of years the original investment remains as it was at the beginning."

This language clearly defines the underlying principles which should govern an analysis of depreciation. Depreciation is an obligation to be met by the rate-payers—the public—at the time when renewals become necessary. Stating the problem in its simplest form, freed from all legal entanglements, and considering only the equity in the case, the following analysis results:

An investor, on entering the public utility business, dedicates his property to the public use, and, in return, the public obligates itself to pay a reasonable rate of return for the use of the property and to restore to the owner the value of any portion of it consumed or wasted in the public service; or, in other words, the public is obligated to make good the depreciation. Suppose, now, that the utility, at the beginning of the enterprise, should accept from the public the promissory notes of all the rate-payers, payable on demand, without interest, the face value of these notes aggregating an amount equal to the reproduction cost of the property, it being stipulated that the payments would be demanded only as required for the renewal of totally depreciated property. If such a procedure were practical, and assuming that these notes were convertible into gold dollars on demand, at full face value, depreciation would thus be provided for; and an appraiser, called on to determine the value of the property for rate purposes, would undoubtedly recognize the injustice of deducting depreciation from the cost of reproduction in any project financed in this manner. Now, the foregoing procedure is exactly what the sinking-fund theory is, except that the investor allows these promissory notes to be paid in small annual payments, just sufficient so that if invested at compound interest, the total sum accumulated at the maturity of the notes (the expectancy of the property life), will equal their face value. The investor, therefore, in accepting depreciation on the sinking-fund basis, does not in fact, so far as its use value is concerned, have any of his available capital returned to him until the end of the life of the structure, and in order that he may receive a fair return on the value of his property, the rates must be based on the reproduction cost of the property, undiminished by depreciation. If the investor chooses to reinvest the cash on hand in the depreciation fund at any time, with the hope of securing greater returns therefor, he must assume the risk and incur the liability of returning the amount withdrawn

Mr. Burns. plus its accumulations at compound interest when necessary for renewal expenditures; for example, if he is collecting depreciation on the sinking-fund basis, where 4% is considered a fair rate of interest at which to compound the fund, and he is able to withdraw the fund and invest it in extensions to the property, or elsewhere, and thus realize 8% thereon, the additional 4% is due him as compensation for the effort, risk, and worry inherent to the investment of capital, and the first 4%, being the proper rate for liquid capital, must be considered as going to restore depreciation.

The writer fails to see why any distinction should be made between the case where the sinking fund is actually kept in the bank or in trust and where it is kept merely as a book entry and has been diverted to other investments. In fact, the public, by the fundamental principles on which the sinking-fund theory is based, compels the utility owner to invest the depreciation fund somewhere, where it will draw 4% compound interest, or some predetermined rate considered proper for liquid capital; and how can it matter to the public whether it is invested in time deposits in a bank, in Government bonds drawing the necessary rate of interest, or in private venture where the owner perhaps hopes to realize 10%—and what matters it whether or not his expectations are realized? The public secures its recompense in being permitted to discharge its depreciation obligation by paying into the sinking fund the smaller annual contributions and imposing on the owner the obligation of reinvesting the fund; and the owner secures his reward for reinvestment if this venture proves successful, and he pays the penalty if it is a losing one.

The author states further "that the owner cannot have a return on it [the sinking fund] as a 'sinking fund' for depreciation, * * *, and at the same time have a return on it as a betterment to the plant. This would be an obvious injustice to the public." At first thought this seems plausible, but, on further consideration, is it not a fact that the contrary is the case, namely, that the public in reality owes this opportunity for reinvestment to the utility owner?

The public, having imposed on the public utility owner the necessity for reinvestment of the fund where it will earn, say, 4% interest, should in equity open the avenue of investment to him when the opportunity presents itself. To illustrate further, take the simplest case imaginable; for instance, a gravity system of water-works, where the entire property consists of \$100 000 worth of wood pipe, having a life of 20 years; the utility owner dedicates this \$100 000 to the public service, and, in return, the rate-payers obligate themselves to pay a reasonable return on the investment, and to preserve the property intact; or, in other words, make good the waste from usage. The rate-payers provide for the depreciation by giving their promissory notes aggregating \$100 000 in face value, payable 20 years after date,

without interest. The utility owner permits these notes to be paid in annual installments on a 4% sinking-fund basis, payable at the beginning of each year, or at the rate of \$3 229 per annum; and it so happens that the betterments, which in this instance are for extensions to the pipe system, require the expenditure of \$3 229 per year. The rate-payers, in consideration for being allowed to care for depreciation by paying the sum of \$3 229 annually, permit, and, in fact, compel, the utility owner to reinvest this sum of \$3 229 annually where it will earn 4% compound interest, and they also require him to invest this or some other \$3 229 annually in pipe lines for extending the service to new territory; but they pay him extra in consideration for these new extensions an amount equal to 3.229% to restore depreciation and, in addition thereto, a reasonable return on these further sums invested annually. Mr. Burns.

Two courses are open to the investor: he may leave the first \$3 229 annually in a trust fund, earning 4%, in some reliable bank, and use \$3 229 annually of his other resources in extensions, or, he may expend the \$3 229 depreciation fund directly for extensions. In the former case he will find his situation in 20 years to be as follows:

He will have \$100 000 in the trust fund with which to replace the original pipe system, and he is also in possession of \$100 000 worth of extensions paid for from his outside resources. In the latter case, he will find at the end of 20 years that he has \$100 000 worth of pipe requiring replacement, with no funds in trust, but he has the \$100 000 in his outside resources which he may as well now spend all at once instead of at the rate of \$3 229 annually, as was done in the former case. He also has the same investment in extensions or betterments as in the former case. Hence, the owner's financial situation is exactly the same at the end of 20 years regardless of which method of finance he chooses to pursue. The public is likewise in identically the same position in either case; for, had the owner left the depreciation account in trust until the \$100 000 had accumulated, at the end of 20 years that sum is due the owner in exchange for his worn-out property, dedicated and consumed in the public service. Hence, the public could have no claim on the sum, nor title to any portion of it. Neither the owner of the utility nor the public being in any wise affected by the owner's withdrawal of the sinking fund for reinvestment or for extensions of the property, it would seem proper that the valuation for rate purposes should be the same in either case, no matter whether the sinking fund is left in a trust fund or used for private venture. If the amount of depreciation to be set aside annually is computed on the sinking-fund theory, it seems, therefore, that no deduction can equitably be made from reproduction cost in arriving at the proper valuation to use as the basis of rates. The rate-payers, therefore, should contribute annually \$3 229 for depreciation and the reasonable

Mr. Burns. rate for interest and profits to the owner, regardless of whether or not the depreciation fund is held in reserve.

The writer, therefore, can see no reason in equity for the conclusion that any injustice to the public results from allowing the owner of the utility to have return on the sinking fund for depreciation at the proper rate of interest for such depreciation accounts, and at the same time have return on it as betterment to the plant, for each betterment to the plant simply means a larger investment or larger plant on which the owner is entitled to the proper reasonable rate of return. Doubtless what the author had in mind was that it would be unjust to allow the owner to reinvest the sinking fund in betterments and receive thereon, say, 8% net return, and, at the same time, receive 4% as sinking-fund accumulation. It seems to the writer, however, that when the owner invests his sinking fund in betterments, or in private enterprise, and thereby receives 8% return, he in fact does not receive 8%, but, on the contrary, receives only 4%, because half of this 8% return does not represent profit but simply goes to restore to him some of his property already consumed by the public in the public service.

If a community constructs a utility under municipal ownership, it is almost universally the custom to pay for such a utility by a bond issue. Now, to determine the basis of rates in such a municipal enterprise, in order that it shall be made exactly self-supporting, with no surplus, the amount of the original bond issue is always taken as the basis on which the community must pay interest, assuming that the sinking fund with which to pay off the bonds is based on an expectancy equal to the life of the property; that is to say, if the bond issue runs for the number of years represented by the life of the property, the community must set aside a sinking fund sufficient to pay off the bonded indebtedness, and must likewise continue to pay interest on the full amount of the bond issue, regardless of the fact that the property itself is continually depreciating in value. In fact, this method of financing the enterprise is absolutely essential if the project is to be made self-sustaining. How, then, can there be any escape from the conclusion that a privately owned utility must receive its return on the same basis, for to receive less will undermine the integrity of the investment, and is, therefore, not a fair return. Of course, if the municipal bond issue is to be paid serially, then the amounts paid off from time to time would be deducted from the capital on which the public must continue to pay interest, but in order to pay these bonds serially, the annual levy or contribution for sinking-fund purposes must be largely in excess of the amount necessary for the application of the sinking-fund theory. It would seem, therefore, that the proper deduction to make from reproduction cost is simply the amount by which the actual depreciation allowance exceeds the theoretical accu-

mulation in a sinking-fund account, computed on the age and life of the property. If depreciation is figured on the sinking-fund basis only, therefore, no deduction should be made from reproduction cost. Mr. Burns.

The Public Utilities Act of California, in effect March 23d, 1913, provides, in Section 49, that:

"The Commission shall have power, after hearing, to require any or all public utilities to carry a proper and adequate depreciation account in accordance with such rules, regulations and forms of account as the Commission may prescribe. The Commission may, from time to time, ascertain and determine and by order fix the proper and adequate rates of depreciation of the several classes of property of each public utility. Each public utility shall conform its depreciation accounts to the rates so ascertained, determined and fixed, and shall set aside the moneys so provided for out of earnings and carry the same in a depreciation fund and expend such fund only for such purposes and under such rules and regulations, both as to original expenditure and subsequent replacement as the Commission may prescribe. The income from the investments of moneys in such fund shall likewise be carried in such fund."

With the administration of the depreciation fund in accordance with this Section of the California Act, it would seem that such fund must be kept separate and set aside, and as far as the owner of the utility is concerned, he has no discretion whatever over its disbursement, and he cannot withdraw such fund for any purpose other than for the replacement of depreciated property. Therefore, depreciation cannot equitably be deducted from the cost of reproduction in California rate cases when that method is used to determine the value of the property.

Section 47 of the Public Utilities Act of Idaho, and also Section 79 of the Public Utilities Act of Missouri, use almost exactly the same language as the California Section already quoted. This indicates the tendency in recent legislation to require public utility companies to set aside sinking-fund accounts, or, in other words, it takes these accounts out of the hands of the public utility owners and leaves them largely under the control of the public through its representatives, the public service commissions. There can be no objection to leaving the collection and disbursement of the sinking fund entirely under public control through proper utility commissions, and, in fact, it is highly desirable that such should be the case, but it is important that the commission should study carefully the conditions surrounding each property in order that the amount of depreciation collected from the rate-payers, and thus set aside, shall be adequate and equitable under all the circumstances.

Contingent depreciation should receive special consideration in each case, its amount depending on the nature of the property. Contingent depreciation is the sum that should be provided from earnings

Mr. Burns. to meet unusual or unexpected replacements which become necessary from time to time in the experience of every public utility, such, for example, as damage from floods, destruction of property by earthquake or ice gorge, failure of water supply, and many similar experiences. Depreciation by obsolescence or changes in the art should also be fully covered by the allowance for contingent depreciation. In fact, contingent depreciation may be defined as the sum that should be provided for insurance against such contingencies as cannot be covered by any class of commercial insurance. This raises an important question: Is the sinking-fund method of computing the depreciation fair to the owner of a utility in a rate-regulation investigation? Evidently not, unless the rates are based on the cost of reproduction undiminished by depreciation, but, under the usual procedure in a rate investigation, it is extremely difficult, if not utterly impossible, to receive consideration for the full reproduction value of a public utility, and would it not be more practical, therefore, to adopt some system of accounting depreciation that will secure equity to both parties when considered in conjunction with a proper rate of return on the remaining expectancy of the property? Perhaps this can be understood more clearly by considering the property as passing through a series of successive ownerships. It cannot be denied that the owner may sell the property at any time and retain the accumulated depreciation fund. This fund is due him, for, if he sells the property at its fair value, computed on the sinking-fund basis, he must retain the depreciation fund in order to recover the full amount of his investment.

Consider again the case in its simplest form, the gravity system of water-works previously cited, and, for the purpose of simplicity, assume that no extensions or betterments are required throughout the 20 years' life of the property, and that no elements of appreciation in value accrue to affect any portion of the works. The first owner should receive from the rate-payers the sum of \$3 229 for depreciation and a reasonable return on his investment of \$100 000. He sells the property at the end of the first year at its value, computed on the sinking-fund basis, namely, \$96 771. The second owner should receive from the rate-payers for depreciation the sum of 3.475% of his investment of \$96 771, or \$3 362.79—this being computed on the basis of the remaining life of the property, 19 years—and, in addition thereto, he should receive a reasonable rate of return on the reduced capital account, \$96 771. Now, if such a rate is equitable to each of the successive owners of the property, it must be equally fair to the public and to the owner throughout the life of the property, if the same ownership continues throughout the entire period. For the purpose of illustration, Table 3 is submitted, computed on the basis of 4% compound interest on the depreciation fund, 8% for interest and profit on the capital investment, and a variable allowance for contingent

depreciation, starting at 2% of the capital account and increasing as the property becomes older, the amount of increase being such as to preserve a constant total contribution from the rate-payers. It is desirable, from the point of public expediency, that rates be not fluctuating, and this may be accomplished by the variable contingent depreciation, based on an amount that shall represent, as nearly as can be predetermined, the facts in each case under consideration. Mr. Burns.

TABLE 3.

Owner.	Capital invested.	Depreciation. Rate. Per cent.	Depreciation. Amount.	Interest and profit. 8%.	Contingent depreciation.	Annual cost to rate-payers.
1st........	$100 000	3.229	$3 229	$8 000	$2 000	$13 229

20th........	7 974	96.154	7 667	638	4 924	13 229

An examination of the column in Table 3 headed "Contingent Depreciation", shows that the variation in contingent depreciation from year to year is not great, under this system of accounting, and represents very closely what may be reasonably expected, increasing gradually with the age of the property. The contingent depreciation is not a cumulative fund, but, on the contrary, represents the amount actually spent from time to time in replacing obsolete or abandoned property and in repairing damage from unexpected or unusual causes. If properly proportioned, such a fund will fluctuate between surplus and deficit, but will maintain a general average near the zero line. The actual figures used in Table 3 are, perhaps, not appropriate for a property of this nature, but are submitted simply to illustrate a principle and without reference to the adequacy, or otherwise, as this can be determined only by a study of all the circumstances surrounding each particular property. The table is based on annual contributions to a sinking fund at the beginning of each year, although many authorities prefer using the tables computed for the end of the year. Rates are usually collected quarterly or monthly and, therefore, as

Mr. Burns. a matter of fact, it would more nearly accord with correct theory to use tables computed for annual contributions in the mid-year, if such tables were at hand. However, this difference is not sufficient to cause material error in any event.

Unfortunately, in actual practice, the problem is never so simple as the gravity water-works system used in this illustration. Public utility enterprises are, from the very necessity of the case, almost continuously extended from year to year, so that the average age of a property of this nature never even remotely approaches that of its oldest parts.

If the theory outlined herein is accepted as a correct method of computing depreciation, its practical application would be somewhat as follows:

The appraiser would determine the composite life of the utility under consideration, which, for illustration, in the case of a water-works system, in some particular case might be found to be 60 years. The average age of the entire property, computed in like manner, might be found, for example, to be 20 years. The rate to be used in determining the amount of ordinary depreciation therefor would be based on an expectancy of 40 years. On a 3% sinking-fund basis, this would be 1.288%—this percentage to be applied to the remaining capital determined by deducting the sinking-fund accumulation of 20 years from the cost of reproduction of the property. The proper additional amount to be allowed for contingent depreciation, of course, should be determined by the particular circumstances in the case. It would be more precise to compute the result separately for each group of items having the same age and estimated life; but such a procedure would, perhaps, be impractical in most cases, owing to its difficulty of application.

Mr. Knox. STUART K. KNOX, M. AM. SOC. C. E. (by letter).—Mr. Alvord's paper, dealing with "the general relation of depreciation and its effects on the fair return of a utility property," will have justified itself if it does no more than precipitate the extended discussion of this interesting and intricate subject, concerning which ideas are at present so confused and conflicting. In this, it appears to the writer, will lie its chief, if not its only, value.

As the author implies, there exists at the present time a wide diversity of opinion among engineers, lawyers, special masters, commissions, and Courts having to do with valuations for rate-making purposes, with regard to the fundamental question of the value on which fair rates should be predicated.

Among those who have sought to sustain the reproduction-cost-new theory may be mentioned the special master,* *re* Columbus Railway

* Robert H. Whitten. "Valuation of Public Service Corporations," p. 368.

and Light Company *vs.* City of Columbus, Ohio, 1906; the Wisconsin Railroad Commission,* *re* City of Whitewater *v.* Whitewater Electric Light Company, decided December 16th, 1910; Massachusetts Joint Board,† Massachusetts Appraisal of the New York, New Haven, and Hartford Railroad, 1911; C. E. Grunsky,‡ M. Am. Soc. C. E., in his paper entitled "The Appraisal of Public Service Properties as a Basis for the Regulation of Rates", to which paper the author refers; and Alexander C. Humphreys, M. Am. Soc. C. E.,§ President of the Stevens Institute of Technology, in his paper entitled "Depreciation: Estimated and Actual", presented before the Institution of Gas Engineers of Great Britain, 1913. Mr. Knox.

The contrary view, to the effect that fair rates should be adjusted to yield a fair return only on depreciated reproduction-cost, has been upheld by the Oklahoma Supreme Court,‖ *re* Pioneer Telephone and Telegraph Company *v.* Westenhaver, decided January 10th, 1911; by the New York Public Service Commission for the First District,¶ *re* Metropolitan Street Railway Reorganization, decided February 27th, 1912; and by the United States Supreme Court.

Mr. Alvord's ideas on the subject are summarized in his first and second "conclusions," as follows:

"1st.—That if a sinking fund or a reserve fund for depreciation is actually kept in the bank or in trust as part of the property, it should, if properly computed and accurately kept, receive the same rate of fair return as the remainder of the property 'used and useful for the public'.

"2d.—That if these funds are for any reason detached or withdrawn from the property and used by the owner elsewhere, or in private gain, or even as new capital invested in the plant itself, he cannot hope, as a matter of proper protection to the public, to receive return on a reserve fund which is not actually in hand and at the same time use such funds for other personal gain."

The writer is not prepared to admit the truth of either of these propositions without material qualification, and in the following discussion will seek to show:

(*a*) That the disposition made of the depreciation reserves has theoretically no bearing whatever on the question of value on which the owner of a utility property is entitled to earn a fair return.

(*b*) That the question of value on which an owner is entitled to earn a fair return depends solely on whether the depreciation reserve provided has been or is to be just "adequate", "excessive" in amount, or "inadequate" for the purpose intended.

Mr. Knox. He will endeavor to demonstrate that when the depreciation reserves, which have been and are to be provided, are just "adequate" for the purpose intended, the owner must, if he is to be protected against the impairment of his capital or of its earning power, be permitted to earn, in addition to operating expenses and this "adequate" depreciation reserve, a fair return on reproduction-cost-new.

That when the depreciation reserves, which are to be provided, are "excessive", so as virtually to effect a refund to the owner of a portion of his original investment, together with its full earning power, rates may be equitably adjusted to yield a fair return on a value less than reproduction-cost-new, the measure of the reduction being the total amount of the capital so refunded.

That when the chosen method of providing for future depreciation is such as virtually to effect a progressive refund, free and clear, of a portion of the owner's original investment, a corresponding progressive decrease in the value on which he is allowed to earn a fair return may be equitably made.

That when the depreciation reserves which have been provided are "excessive," so as virtually to have effected a refund of a portion of the owner's original capital, rates may be equitably adjusted to yield a fair return on a value less than reproduction-cost-new only if no change in ownership has taken place.

That when the depreciation reserves which have been provided are "inadequate", so that an actual impairment in capital has taken place, we should, to be consistent, and provided full ownership is still retained by the owner who suffered the loss, permit the adjustment of rates to yield a fair return on a value greater than reproduction-cost-new until this loss has been recouped.

That rates may be equitably adjusted to yield a fair return on depreciated reproduction cost, only if the virtual refund of capital, resulting from "excessive" past or prospective depreciation reserves, just equals the accrued depreciation on the property on the date of the valuation for rate-making purposes.

As a preliminary to the intelligent discussion of the preceding propositions, it is essential first to define exactly what is meant by "adequate", "excessive", and "inadequate" depreciation reserves, and by the expressions "accrued depreciation" and "depreciated reproduction cost".

By "adequate" depreciation reserve is meant the annuity or percentage of reproduction-cost-new which, if set aside in the bank or in trust from the beginning of operation, at the rate of interest, say 4%, on which the fund payments are predicated, will, with all interest accretions, amortize a sum which, at the termination of the useful life of each element of the property, will just suffice to replace it and no more.

By "excessive" depreciation reserve the writer means an annuity greater in amount, and by "inadequate" depreciation reserve an annuity less in amount than the above. Mr. Knox.

By "accrued depreciation" at any period of the life of a property, is meant the amount which an "adequate" depreciation reserve would have amortized had it been set aside each year from the beginning of operation.

By "depreciated reproduction cost", is meant the reproduction-cost-new less the "accrued depreciation" so determined.

By the "useful life" of any element of property, is meant its age plus the remaining life expectancy of the element.

In explanation and justification of the foregoing definitions, it may be well to digress at this point to the extent of acknowledging a full realization of the fact that any estimate of accrued or prospective depreciation is at best a guess. There are, however, intelligent guesses and unintelligent guesses, and there are intelligent ways of guessing and unintelligent ways of guessing. One unintelligent way of guessing the accrued depreciation on a pumping engine, for example, is to sit in the office and compute it, starting with the assumption that the normal life expectancy of a new unit of the type considered is 20 years, and that the age of the particular unit under consideration is, say, 10 years. The unit may have been in continuous service from the date of its installation, or it may have been used largely as a spare. It may have been operated 24 hours per day, or only 1 or 2 hours per day. It may or may not have had intelligent care, and it may or may not be well adapted to the service, well designed, and of modern type. No intelligent guess of accrued or prospective depreciation can be made without a visual field inspection of the element to be appraised.

Whatever be the age of a unit, or structure, the present value of which it is desired to ascertain, the uncertain element affecting this value which may be guessed most accurately by an expert is its remaining life expectancy. In the light of the history and probable future of the plant, of the community which it serves, and of the arts, this, after an examination of the unit or structure, may be gauged as closely as any other probability affecting the future of the property. Then, if the guess proves accurate, the "useful life" of the element becomes its age plus its life expectancy on the date of the appraisal; and an "adequate" allowance to cover annual depreciation is the annuity, which, had it been paid into a fund each year since the installation or construction of the unit or structure, would have amortized a sum sufficient to reproduce it at the end of this "useful life". Under these conditions the "accrued depreciation" on the date of the appraisal may fairly be estimated as the amount which such an annuity would have accumulated between the date of installation and the date of the appraisal, and its fair market value or depreciated reproduction-cost

Mr. Knox. at the date of appraisal may fairly be assumed to be its reproduction-cost-new less the accrued depreciation so found. Fair market value under these circumstances would of course be defined to be the value as established between a seller who was willing but not compelled to sell and a buyer who was willing but not compelled to buy.

In all that follows, it will be assumed that the guesses as to life expectancy and hence of proper or "adequate" depreciation reserves are accurate ones.

To come to the discussion of Mr. Alvord's conclusions, it is undoubtedly true as the author states that "there must be in this, as in all other questions relating to this difficult subject of valuation, a just and equitable relation between the public and the public utility owners, which is founded on rational analysis and common sense." In seeking out this relation much is gained in the way of clarity by confining ourselves at first to the consideration of simple examples. We are thus able to eliminate the many complicating, confusing, and often entirely irrelevant considerations which usually cloud and obscure the vital principles involved, when the question is studied in the light of complex cases such as commonly come before the Courts. Although it is no doubt true, as the author implies, that conclusions deduced from the consideration of simple examples will not always admit of indefinite extension to cover the complex cases met in actual practice, we seem at least to be on safe ground in assuming, as a point of departure, that a conclusion which will not withstand the most searching analysis, when viewed in the light of its application to a simple practical example, cannot be the basic principle or relation which we are seeking. At any rate, let us grant the truth of this proposition for the moment, and observe the result of applying such a test to the conclusions reached by Mr. Alvord, beginning with his first conclusion, "that if a sinking fund or a reserve fund for depreciation is actually kept in the bank or in trust as part of the property, it should, if properly computed and accurately kept, receive the same rate of fair return as the remainder of the property 'used and useful for the public'."

If by a "properly computed and accurately kept" sinking fund, Mr. Alvord means an "adequate" depreciation reserve, as defined in a preceding paragraph of this discussion, the logic of this conclusion appears to be unassailable.

Consider, for example, a water-works plant, consisting solely of a pipe line 10 miles long. The owner of this property, we will say, buys water at wholesale at one end of the pipe line, and sells it at wholesale at the other end. The writer has in mind a private water company the property of which is substantially as described. Assume that the reproduction-cost-new of the pipe is \$1 000 000, its useful life 50 years, and its scrap value nothing. No part of the line will require replacement during its 50-year life, and the pipe may

Mr. Knox.

be maintained in good serviceable condition throughout the entire period by making such ordinary repairs as may be properly charged to operating expense. Neglecting the fact that the creation of a sinking fund must lag one year behind the commencement of operation, the proper annual reserve to cover depreciation, estimated on a 4% sinking-fund basis, is \$6 550, which amount the owner places in bank each year at 4% compound interest.

In the construction of this pipe line, the owner converted \$1 000 000 of money into physical plant. As the pipe ages, it depreciates in value, and if the guess as to its useful life (50 years) proves correct, the amount of this depreciation is, as nearly as may be, represented at any time by the accumulation in the sinking fund or reserve fund for depreciation. The process may be regarded as the gradual re-conversion of plant value into cash, until at the end of the pipe's useful life the owner has all cash and no pipe line, at which time the money accumulated is again converted into physical plant through the taking over of a new pipe line which the owner has caused to be constructed. At any intermediate period of the life of the pipe, the owner's capital is represented partly by the depreciated value of the line, and partly by the depreciation reserve. The sum of the two may be considered as representing at any time the reproduction-cost-new. A purchaser can at any time afford to pay for the pipe line and depreciation fund together, a sum equal to the pipe's reproduction-cost-new, for by continuing the depreciation reserve in bank, and adding the proper annual payments, as these are earned, he will have available at the termination of the useful life of the property a sum equal to his original investment and to the pipe's reproduction-cost-new. This is equivalent to saying that a purchaser can at any time afford to pay for the pipe line alone a sum equal to its reproduction-cost-new less the accumulations in the sinking fund, or its depreciated reproduction cost.

Now, as all interest accretions, if the annual depreciation reserve is a proper or "adequate" reserve computed on the sinking-fund basis, must be credited to the fund, the owner enjoys no income therefrom, and, therefore, should be allowed to earn a fair return on the depreciated physical value plus the depreciation reserve, or on the reproduction-cost-new. To assert the contrary is to assert that the owner must, in spite of everything he can do, suffer a financial loss through impairment of the earning power of the capital which he has invested.

Let us now examine Mr. Alvord's second conclusion:

"That if these funds [adequate depreciation reserves] are for any reason detached or withdrawn from the property and used by the owner elsewhere, or in private gain, or even as new capital invested in the plant itself, he cannot hope, as a matter of proper protection to the public, to receive return on a reserve fund which is not actually in hand and at the same time use such funds for other personal gain."

Mr. Knox.

Suppose that the owner of the pipe line operates his plant in exactly the same way as described, except that instead of actually placing \$6 550 in bank or in trust each year as part of the property, he invests this amount in other ways, or even places it in a safe deposit vault, or squanders it. Mr. Alvord concludes that under these circumstances rates may be equitably adjusted to yield a fair return only on the depreciated physical value of the pipe instead of on its reproduction-cost-new. This means that unless the annual depreciation reserves are correspondingly increased above the "adequate" amount previously estimated, a sliding scale of rates must be introduced, such that the amount available for interest in the tenth year of operation, after deducting operating expenses and depreciation reserve, will be approximately 92%, in the fortieth year approximately 38%, etc., of its amount in the first year of operation. As the service is now by hypothesis exactly the same as in the case where the depreciation reserve was actually deposited in bank as part of the property, the water consumer will evidently gain in reduced rates by the owner's failure to establish an actual depreciation reserve. It is equally evident that the consumer cannot gain unless at the same time the owner loses an equal amount. Let us pursue the illustration further.

Suppose that the owner, in the tenth year of operation, becomes alarmed at the dwindling profits on his water transportation business, and begins to busy himself in devising a plan for restoring rates to the point where they will yield the same return on his capital as in the first year. He estimates that if he had from the outset maintained a depreciation fund in the bank at 4%, the accumulations in this fund would at the end of the tenth year have amounted to \$78 760.56. He, therefore, sells at par from his private means seventy-nine \$1 000 municipal bonds drawing 4% interest, or he sells, we will say, an apartment house valued at \$78 760.56, which has been yielding him a net return of 4% per annum. He deposits the proceeds, \$78 760.56, in the bank at the beginning of the eleventh year and christens it a depreciation fund. He has not lost a dollar by this transaction. The depreciation fund is his property in the same way that the house was his property. The interest yield is the same. He has simply performed the familiar operation of taking a sum of money out of one pocket and placing it in another, and yet, as a result of this simple shifting of assets, he has placed himself in a position where he may equitably charge his customer, the water consumer, we will say, an additional \$10 per 1 000 000 gal. for exactly the same quantity and quality of water, delivered under exactly the same pressure as before the depreciation fund was created. Could anything be more absurd?

Mr. Alvord speaks of the use of the depreciation reserves, by the owner, "for other personal gain". It is, of course, apparent that when these reserves are proper or "adequate" reserves computed on the sink-

ing-fund basis, it is entirely beyond the power of the owner to use them so as to yield "a private gain", unless he invests them in a way to yield a return greater than that which they would have earned if placed in the bank or in trust at the rate of interest on which the sinking or depreciation fund payments were computed. Mr. Knox.

If correctly computed on the sinking-fund basis, the sum of the annual reserves will, by hypothesis, produce an amount sufficient to provide for future replacements, only if credited with all interest accretions resulting from their conservative investment. The source of these interest accretions is immaterial. The funds are equally unproductive, as far as concerns their power to yield a "private gain" to the owner, whether they be placed in bank at 4% interest, invested in high-grade municipal bonds at 4% interest, or invested in other ways. If the owner is fortunate enough to invest them in a way to yield a return greater than they would have earned if placed in a bank or in trust, his "private gain" is represented, not by the total yield of the funds so invested, but only by the excess of this yield over and above what they would have earned if placed in the bank or in trust. To obtain this excess yield or "private gain", the owner performs services and assumes risks for which he is entitled to compensation represented by the excess yield. He has, in fact, entered the banking business and is as much entitled to a fair profit on this banking business as he is on his water-works business. In his capacity of water-works manager, he deposits with himself, in his capacity of banker, the depreciation reserves on which he pays 4% compound interest. When the time arrives, he must return these sums with accumulated interest, the same as any other banker would be obliged to do. In the meantime he is entitled to invest them conservatively in such a way that they will yield enough more than 4% to compensate him for performing the services and assuming the responsibilities and risks which attend the banking business.

There are bankers and trust companies, many of them, that actually own and operate water companies. Is it to be presumed that these banking institutions, to avoid being "fined," must invest their depreciation reserves with some competitor, perhaps less responsible and competent than themselves? Again, the proposition is absurd.

Theoretically, the consumer has no interest whatever in the depreciation reserves or in the disposition which is made of them. He is interested only in the quality of the service. Service is what he pays for. He pays, not for the quality of service which an element of plant is capable of rendering when new, or at its absolute maximum of efficiency, but for the average service which it is capable of rendering during the period known as its "useful life," when maintained throughout this life in the highest state of efficiency which is physically possible, and replaced at its termination with a new ele-

Mr. Knox. ment. In the absence of certain knowledge to the contrary, it must be presumed that the owners will so maintain and so replace the plant, regardless of whether or not an actual, tangible depreciation fund is maintained in a bank—a competitor's bank. Even when depreciation reserves have been distributed to stockholders, or lost or tied up in unfortunate investments, it must be presumed, in the absence of certain knowledge to the contrary, that the owners will provide funds as required by dividend reductions, assessments against the stock, or in extreme cases by reductions in interest.

As a practical matter, it is granted that in certain cases the owner's failure to invest depreciation reserves conservatively may react on the consumer, and that to this extent he is interested in the disposition which is made of them. It is, for example, a matter of common observation and knowledge that when an owner first becomes involved in financial difficulties there exists the temptation and tendency to maintain dividends and interest at the expense of maintenance and replacements. The prevention of this is one of the functions of the regulating power.

As long as the quality of the service is actually maintained, there can exist no logical reason why the value on which the owner of a property is entitled to earn a fair return should be variable, depending on whether or not a reserve for depreciation is maintained in the bank or in trust as part of the property. To penalize or "fine" an owner for failure to maintain an actual fund by adjusting rates to yield a fair return only on depreciated reproduction-cost, is to presume in advance of the fact that he will not, when required, and at his own cost, make the replacements for which depreciation reserves were provided. It is in effect to punish him in advance for an offense that it is suspected he may commit at some time in the future.

The points just made have been clearly stated by the Wisconsin Railroad Commission *re* City of Whitewater and Whitewater Electric Light Company, decided December 16th, 1910.* The Wisconsin Railroad Commission says:

"As it is a general rule that the reasonable return which a utility is allowed to earn covers the interest and depreciation on the actual investment in the plant, it becomes important to know what the investment in the plant actually is—that is, what is the value of the plant new. The fact that the property of the utility has diminished in value with use, as the inevitable result of depreciation, does not lessen the amount of the investment in the plant. To be sure, it may happen in the case of a given utility that money which should have gone to the establishment of a depreciation fund has been diverted to the stockholders, thereby apparently lessening their investment. If an amount equal to the difference between the value of the plant new, and the value in present condition is thus paid over to stockholders, it would

* Robert H. Whitten, "Valuation of Public Utility Properties," p. 366.

appear, at first sight, that the value of the plant in present condition would be the basis on which interest returns should be allowed. But it must not be forgotten that at the expiration of the life of the plant if the money which should have been used to provide for depreciation has been paid to stockholders in the form of dividends or otherwise, the value of the plant will be nothing. Then, instead of the utility having a depreciation fund on which to draw to replace the plant, the owners will find it necessary to pay the cost of replacement, presumably from the money which they have received from the plant, but which should have been used to provide a depreciation fund. The investment in the plant then must, in general, be taken at the cost of the plant new, since although the investment may apparently be diminished by failure to provide for depreciation, and by the payment of this money to owners or stockholders, in reality the investment is not diminished, because of the necessity of replacing the plant, in the absence of a depreciation fund, from the property of owners or stockholders. Therefore, it appears that the question of valuation, which is of most importance in the case, is that of cost of the plant new, or the actual value of the total investment in the plant." Mr. Knox.

It is not necessary to state that a reduction, below reproduction-cost-new, of the value on which an owner is permitted to earn a fair return, may be logically justified only on the assumption that a virtual refund of a portion of the capital originally invested has taken place prior to the date of the valuation for rate-making purposes. It has been shown that no such refund is effected where an owner, in lieu of maintaining an actual tangible depreciation fund in the bank, invests these reserves in other ways. There are, however, ways in which such a virtual refund may occur, and it may prove interesting to examine one or two of them.

Suppose, for example, that the owner of the pipe line, previously referred to, instead of setting aside each year in addition to operating expenses and interest an "adequate" depreciation reserve of $6 550, sets aside a depreciation reserve, improperly computed on the straight-line basis, of $20 000 per year. Under these circumstances interest accretions are no longer, of necessity, credited to the fund, for the sum of the annual payments themselves, will, without interest, accumulate an amount sufficient to replace the pipe line at the end of its useful life. Whether placed in the bank as an actual tangible depreciation fund, or invested in other ways, the owner may each year draw and add to his gross earnings the income from this fund without in any way defeating the object for which it was created. However it be invested, the entire fund may now be used productively by the owner "in private gain." A portion of his original investment equal in amount to the sum of the annual depreciation reserves has in effect been refunded to the owner by the consumer. It has been refunded free and clear, together with its full earning power, and if the owner is to be prevented from receiving, at the expense of the consumer, a double interest return

Mr. Knox. on the same principal, rates must be adjusted to yield a fair return, not on reproduction-cost-new and not on depreciated reproduction cost, but on reproduction-cost-new less the sum of the "excessive" annual depreciation reserves. This value will be less than the depreciated reproduction cost. At certain periods during the life of the pipe, it will be materially less. At the end of the twenty-fifth year, for example, the "accrued depreciation," or the sum amortized by an "adequate" depreciation reserve of \$6 550 per annum, will be only \$272 803, whereas the sum of the annual depreciation reserves, without accrued interest, will be \$500 000. The depreciated reproduction cost on that date will be \$1 000 000 — \$272 803 = \$727 197, whereas the value on which the owner should be allowed to earn a fair return will be only \$1 000 000 — \$500 000 = \$500 000, or about two-thirds of the depreciated reproduction cost.

If an owner has, during the past, set aside out of earnings an "excessive" annual depreciation reserve, or if he has, what amounts to the same thing, enjoyed excessive profits, it may appear from the preceding discussion that the ends of justice will be served by adjusting rates to yield a fair return on a value less than reproduction-cost-new. The justice of the procedure, when adopted as a retroactive or punitive measure, is, however, only apparent. The ownership of most public utility properties is constantly changing through transfers of stock, and reprisal would in many cases fall, not on the original owners, who alone could be supposed to merit it, but on the present owners who purchased in good faith, at a fair price, and reaped no benefit from past extortions.

Suppose, for example, that at the end of the twenty-fifth year, and just prior to the date of a valuation for rate-making purposes, the pipe line, previously referred to, had been sold by the original owner, A, to the present owner, B. Suppose that A, throughout the period during which he operated the line, had extorted from the public, in addition to a fair return on his capital, improper depreciation reserves estimated on the straight-line basis, which amounts he did not transfer to B with the depreciated property. A has now placed himself beyond the reach of reprisal. He has gone out of the waterworks business, taking his unholy profits with him. He has sold his plant for its market value which, for the purposes of this discussion, may be assumed to be fairly represented by its depreciated reproduction cost at the date of sale (\$727 197). He could not have sold it for more however moderate his early charges for depreciation had been. B has purchased the property in good faith and for a fair price. It might now be argued superficially that as far as B is concerned, the price paid represents his total investment, and that the adjustment of rates to yield a fair return on this purchase price will impose no hardship on him; but this is not the case. The fallacy in the reason-

ing, though perhaps not obvious, lies in the assumption that the money which B has paid to A for the physical property represents his total investment in plant. It does not. A has sold to B a depreciated physical property plus a liability. The liability consists in the obligation which B incurs of replacing the depreciated pipe line at the end of its useful life. To place himself in a position to meet this obligation when it matures, B must, on the date of the purchase, set aside in bank at 4% interest an amount ($272 803) equal to the accrued depreciation on the plant. If he fails to do this, he, nevertheless, automatically, by the assumption of the obligation, ties up an equal amount of his outside investments as far as concerns their power to yield him a "private gain." In any case his total investment is not represented by the sum of money paid to A, but by this amount plus the accrued depreciation. Whatever disposition he makes of the depreciation reserve, if it is only an "adequate" reserve as previously defined, B will inevitably suffer a financial loss unless allowed to earn a fair return on $1 000 000, the reproduction-cost-new. Any reduction in this value will inevitably work a great injustice by causing B to suffer for the sins of his predecessor. Mr. Knox.

B, it is true, will be protected against loss, if at the same time that rates are adjusted to yield a fair return on depreciated reproduction cost, he is allowed to set aside each year from earnings, an "excessive" depreciation reserve sufficient to reproduce the depreciated plant value ($727 197) at the end of its 25 years of remaining life. It may indeed be laid down as a general rule that where past depreciation reserves with interest accretions have been adequate to take care of the accrued depreciation, and future reserves are made sufficient in themselves to amortize sums which will provide against all subsequent deterioration, rates may fairly be predicated on the depreciated reproduction cost at the date of the valuation for rate-making purposes.

Although there is one notable exception which the writer will discuss later, the adoption of this rule will usually result in difficulties and confusion in accounting, with no attendant benefits either to the consumer or to the owner. Decreasing the amount allowed for interest and at the same time allowing a corresponding increase in amounts allowed to offset depreciation is a mere juggling of figures. An annuity sufficient to amortize the depreciated value of a property at the termination of its remaining life expectancy will become an "excessive" annuity on the day the first replacement is made, and generally the depreciated reproduction cost will be modified as a result of each replacement.

On the other hand, if we neglect the fluctuations in the prices of labor and materials, reproduction-cost-new will remain an unvarying quantity as long as no additions are made to the property, and the "adequate" annual depreciation reserve, estimated in the customary

Mr. Knox. way, will remain at all times a constant percentage of the unvarying reproduction-cost-new. The reproduction-cost-new having once been ascertained may subsequently be kept up to date merely by adding the cost of extensions as these are made, and the "adequate" annual depreciation reserve, having once been ascertained, may be kept up to date, as extensions are made, by adding sums sufficient to reproduce the cost of each such extension at the termination of its useful life.

If past depreciation reserves, with interest accretions, have been no more than adequate to offset the accrued depreciation on the date of the valuation, either method will result in justice both to the consumer and to the owner. The choice of method is merely a question of convenience, and generally it will be found most convenient to predicate rates on reproduction-cost-new, at the same time limiting the annual depreciation reserve to the "adequate" annuity, as previously defined.

The exception to which the writer has referred is presented by the case, briefly touched on by Mr. Alvord, and also discussed by Henry Floy, M. Am. Soc. C. E.,* in which certain large properties, after suffering an initial depreciation, reach a stable stage in which they may afterward be maintained by the expenditure of certain sums each year for replacements, the cost of these replacements being charged to operating expenses the same as ordinary wear and tear. To quote Mr. Floy:

"The Receiver of the Third Avenue Railroad in New York City, operating a large property having numerous physical elements so that all deterioration became simply 'wear and tear' and a part of operating expenses, declined to obey the order of the Public Service Commission and provided no depreciation fund whatever, simply removing deterioration when it occurred and charging it as maintenance in operating expenses."

If past depreciation reserves, with interest accretions, have been no more than "adequate" to offset "accrued depreciation," all subsequent depreciation on a property which has reached this stage of stability, may properly be taken care of in either of two ways:

1st.—By continuing the "adequate" annual depreciation reserve, in which case rates must be predicated on reproduction-cost-new.

2d.—By providing annually, in the manner adopted by the Receiver of the Third Avenue Railroad, a sum sufficient in itself to take care of all subsequent depreciation, in which case rates should be predicated on depreciated reproduction cost.

By the second method the annual depreciation reserve is in excess of an "adequate" reserve, as previously defined, and it is for this

---

* "Valuation of Public Utility Properties," p. 194.

reason, and for this reason alone, that rates may be equitably adjusted to yield a fair return on a value less than reproduction-cost-new. Mr. Knox.

Consider, for example, a plant composed of five elements of equal value and variable life expectancy as shown in Table 4.

TABLE 4.

Element. (1)	Reproduction-cost-new. (2)	Life expectancy, in years. (3)	Annual depreciation reserve to refund reproduction-cost-new at termination of useful life, sinking-fund basis. (4)
A	$1 000	25	$24.01
B	1 000	30	17.83
C	1 000	35	13.58
D	1 000	40	10.52
E	1 000	45	8.26
Total, or average....	$5 000	....	$74.20

Assuming the scrap value to be nothing, the orthodox way of providing for the future depreciation on such a plant would be to set aside each year from the beginning of operation sums sufficient to amortize the reproduction-cost-new of each element at the end of its useful life. The annuities so required, estimated on a 4% sinking-fund basis, are given in Column 4 of Table 4. The total annuity required is $74.20. At the end of the twenty-fifth year, element *A* must be replaced, and the cost will be met by withdrawing from the depreciation fund the $1 000 accumulated by the annuity of $24.01 provided for this purpose; but, as the new element, *A*, will also have a life expectancy of twenty-five years, at the end of which it must again be replaced, the annuity of $24.01 provided to cover depreciation on element *A* must be continued and the total annuity will remain $74.20 as before. It will remain so indefinitely as long as no additions are made to the plant. Whether it be placed in bank or in trust at 4% interest, or invested in other ways, the annuity of $74.20 will, together with all the interest accretions with which it may fairly be credited, just take care of future depreciation, and no more.

Assuming that the owner actually makes such an annual reserve, the amount amortized at the end of the twentieth year will be $2 209.65, which amount may be taken to represent the accrued depreciation on that date. The depreciated reproduction cost at the end of the twentieth year will then be $5 000.00 — $2 209.65 = $2 790.35. As the owner can by hypothesis derive no "private gain" from the depreciation fund, however it may be invested, he must, so long as he provides for depreciation in this way, be allowed to earn a fair return on reproduction-cost-new.
